These ideas were taken by Robert Rescorla and Allan Wagner to create one of the most influential models of learning (Rescorla and Wagner 1972). This model states that learning is the difference between the maximum possible amount of learning about an outcome and the amount of information supplied by all the cues present in the past pairings with the US.

Under this conception, learning could also be considered a function of the difference between what happens and what the subject predicts that will happen. Rescorla and Wagner also proposed that learning depended on the product of how salient or intense the cues and the consequences are, which, according to them, would not change during the course of learning. The result of the equation is a quantitative measure of learning that they called associative value (V).

The Rescorla and Wagner (1972) model was the first to compute the prediction from multiple CSs simultaneously; consequently, it explains several of the competition phenomena observed in Classical conditioning, like blocking. For the model, in the first phase of training, when the first cue is paired with US, the cue becomes a good predictor of the US, but when the second stimulus is added in the second phase, this second cue does not provide much more information about the US: the subject is already good in predicting what is going to happen. In terms of the model, at the end of the pairings of the first cue with the US there is little to no difference between what happens and what the subject predicts that will happen, and when the second CS is introduced, there is little or no more to learn.

The principles of the Rescorla-Wagner model have been taken by several other learning theorists, helping to create many of the current models of conditioning and generating research until today to test the assumptions and predictions of the model.

Mackintosh (1975) and Pearce and Hall (1980) took the basic principle of the Rescorla-Wagner model but added, in two different ways, a new assumption. They assumed that the salience or intensity of the CS, what they called “associability,” would not remain constant across learning trials and it would vary proportionally to

how good of a predictor the CS becomes. These models are commonly referred to as “attentional” models, because of the shared characteristic that the subject will attribute more importance or salience to cues based on their history with the consequences.

Mackintosh (1975) proposed that cues that are better predictors will have a higher associability or attention. If a stimulus predicts a consequence, it should be considered more relevant and thereby should be paid more attention. Due to this, subjects will learn faster associations involving cues that are better predictors of consequences.

Pearce and Hall (1980) model has a seemingly opposed approach to Mackintosh’s to the problem of associability. They proposed that subjects do not need to pay attention to cues that are already known, and are good predictors. Instead, subjects should pay attention to new cues or cues that are inconsistent predictors of consequences. For Pearce and Hall, stimuli that are not good predictors of the CS, for example, before the beginning of training, will have a higher associability or attention, and as the pairings with the consequence continue, the associability will become smaller and smaller. According to the model, learning about new cues when they are paired with the US should be faster than cues that are already good predictors of the US.

The evidence shows that both Mackintosh (1975) and Pearce and Hall (1980) models correctly predict how subjects behave in various circumstances. Both models are able to explain conditioning phenomena such as blocking or latent inhibition. For example, the Mackintosh model states that in latent inhibition, when the CS is presented in absence of any consequence, the subject pays less attention to it because the cue is not a good predictor of the consequence; in the following phase, during the presentations of the cue with the outcome, subjects will take more time to learn the relation between them compared to a cue that was not pre-exposed. Pearce and Hall’s model, on the other hand, assumes that when the CS is pre-exposed, the cue becomes a good predictor of a specific consequence, being that consequence nothing. Here the absence of a stimulus can also serve as consequence after the CS. This

also causes the attention to the cue to decrease but by a different mechanism than for Mackintosh’s model. The result in both cases is the same, the subject will take more trials to learn the CS-US association due to the low associability caused by pre-exposure, but produced by different mechanisms.

Recent developments have tried to reconcile this two, seemingly opposed, proposals creating models that assume that the associability of stimuli can increase in both cases, by being a good predictor of the US and by being an inconsistent predictor of the consequence. These theories are known as “hybrid” models and have been highly discussed in the last years (e.g., Pearce and Mackintosh 2010).

A somewhat different approach was taken by Wagner (1981) who was interested in how representations are formed in memory with his theory of standard operating procedures (SOP). For this theory, stimuli consist of nodes of a number of elements. These elements and by in three different states: an inactive state, and two active states (A1 and A2). Stimuli are normally inactive, but would activate in A1 when they are directly presented. Stimuli can then be activated in A2 either by normal decay from A1 after some time or after learning when an associated cue is presented. After a stimulus is in A2, it can only move to the inactive state. Excitatory conditioning occurs when the two stimuli are in A1, and as learning progresses, the first stimulus starts to activate more and more elements of the second in A2. This theory has been fundamental to explain phenomena like context specificity of latent inhibition, and to make predictions about learning in a real-time base instead of trials as the Rescorla & Wagner model.

Other theories of learning have put focus on how the US is processed by the subject during learning. These theories assume that, in any interaction with the environment, the target US is not a simple stimulus defined by just one dimension or attribute. Consequences are always complex and involve many possible characteristics from which to learn. For example, if the presence of a dog is followed by its bite (possibly causing fear to it), this bite is not just composed by the pain itself, but

it can be divided in different parts like the vision of the bite, the motivational state that it causes (probably non-rewarding), the time of the bite (when the bite occurs both in a general timeline and since the dog was perceived), the response that it causes, and the emotional reaction, among others. Some theories have proposed that we can learn from all these attributes separately and that the rules to learn the relationship between the cue and the consequence may be different for each of its parts (e.g., Delamater and Oakeshott 2007).

Another family of theories views animals as able to learn about the complex environment when several stimuli are in place, and not only about its elements. Each stimulus can be seen as a part of a more complex structure in the subject's environment. Pearce (1987) proposed a model that elaborates on these assumptions. The model states that subjects do not learn about each stimulus separately, but at the moment of learning, they process the environment as a unique complex stimulus composed of every single present cue. Thus, individuals do not learn about relationships between a single cue and the US but about this complex cue (called "configurational stimulus" or simply "configuration") and how that stimulus is related to the consequence.

The Pearce (1987) model states that, during testing, the more similar the configurational stimulus presented is to the one encountered during training, the more the subject will respond to it; conversely, the less similar the test configuration to the original, the less response will be observed (effect known as "generalization decrement"). This model is able to explain several learning phenomena, including cue competition and others.

The theories presented above all assume that subjects respond as much as they learn. In other words, they assume that the response by the subjects is proportional to the acquired learning stated in the equation, which changed during training or acquisition. However, under many circumstances, organisms change their response without further training. The opposite also occurs and is possible to learn without any change in responding; theories of learning have considered how response changes independently of acquisition training,

and how learning can occur without an apparent change in response. Miller and Matzel (1988) provided an approximation to this in the "comparator hypothesis."

Miller and Matzel (1988) suggested that when the subject learns, it does not take in consideration how good of a predictor a cue is (as the Rescorla-Wagner model); instead, the organism learns about all the stimuli that are presented together. In other words, contiguity alone is sufficient to produce learning. Since the subject learns about all present stimuli, responding must be controlled by a different process than the contingency or the associability of each cue. Because the subject is learning via contiguity about every present stimulus, the model suggests that the organism compares which one of all the present stimuli has the strongest connection with the US. When a cue is present, subjects will compare the CS with other cues that were present during training; if the cue is the more strongly associated with the consequence, the subject will respond. Conversely, if other cues have a stronger relation with the US than the CS being presented, subjects will not respond to that CS.

The comparator hypothesis (Miller and Matzel 1988), more specifically, states that in every learning situation (when a cue is followed by a consequence or US), the cue is associated with the consequence, but this cue is also associated with any other stimulus presented during this learning procedure, which causes that when the cue is presented, the subject activates a memory not only of the consequence but also of all other stimuli that were present during training. This memory in turn also indirectly activates a memory of the consequence. When a cue is presented, the subject compares which memory of the consequence is stronger, the directly activated by the cue presented or the one activated indirectly via the memory of the other stimulus presented during testing. Due to this mechanism, the model predicts that once individuals learn, they can change responses without further training being necessary; for instance, if a good competitor that was blocking the response to another stimulus stops being a good competitor, the subject may start now responding to the previously blocked

stimulus. In this situation, acquisition relative to the blocked stimulus has not changed, just the relationship of the competitor stimulus with the CS.

Other family of models have set their focus on the temporal relation between CSs and USs as a central mechanism to learning. Models as the one proposed by Gallistel and Gibbon (2000) share with the comparator hypothesis the notion that responding to a stimulus depends on the comparison between the target stimulus and the background stimuli. However, this model differs from the comparator hypothesis in that it assumes that subjects encode temporal intervals between events and rates of reinforcement instead of a CS-US association. For this model, subjects will respond to a stimulus when the rate of reinforcement of this stimulus is considerably higher than the rate of reinforcement of the context. This and other time-focused models have been proved very useful in many circumstances and have generated a large cluster of research.

All these models and theories here presented have led to an immense increase in the understanding of how organisms learn and what is learned in classical conditioning. Moreover, the different proposals have helped to conceive a great amount of new research to test the models and account for their failures. Nevertheless, the current state of the art is likely far from having a single model that would be able to explain all the phenomena in classical conditioning. More than one hundred years of research have shown that classical conditioning is an extremely complicated cognitive process, which mechanisms can go from considerably simplistic to immensely complex in different situations and under different perspectives.

## A Functional Point of View

Classical conditioning, as presented before, allows organisms to represent themselves their world. It allows subjects to act appropriately and predict many situations in their natural environment, improve their efficiency, and increase their chances to survive. This suggests that classical conditioning is not only a cognitive tool but that

also has a great evolutionary role in the species that learn through it.

The different phenomena of classical conditioning and the mechanisms discussed in previous sections are general across all species where conditioning is observed, and apply to diverse response systems, such as fear, displeasure, pain, taste, sex, etc. This suggests that conditioning has a generalized role in how animals represent their world and is not limited to certain kinds of learning. One classical feature that shows the relevance of classical conditioning in natural environments is that learning between cues that have a “natural” relation to each other proceeds considerably faster than learning between neutral or previously unrelated stimuli. This natural relation between the stimuli can come from a CS that is part of a chain of actions that lead to the US, or of the CS being a feature of the US that initially does not elicit a response; this last case is known as “object” or “part-whole” learning (Domjan 2005). For example, learning to predict that a certain food will cause sickness is considerably easier if the predictor is the flavor of the food than if it is the sound or vision of the food. The use of naturally related stimulus in learning produces not only a faster learning but is also more robust and resistant (Garcia and Koelling 1966). This evidence implies an evolutionary predisposition to learn certain association faster than others, probably due to their importance and relative complementarity between the stimuli. Even more, animals learn to predict events that can be threatening to their lives (e.g., to predict predators, a painful stimulus, or poisoning) faster than less threatening events (e.g., to find a place, tolerance to a drug, or when food would come). From an evolutionary perspective, not learning about the former means a higher chance of dying than not learning about the latter, which would create an evolutionary predisposition to learn about dangerous stimuli faster than to other kind of stimuli.

One example of conditioning with naturalistic stimuli with nonthreatening consequences is sexual conditioning. In sexual conditioning, the sight of a female-like figure or an actual female is paired with access to copulation. Males that are subject to the pairings with the vision of an actual female as

CS are much faster in approaching the female and ejaculating. As in previous examples, when the naturalistic CS is used, learning is less susceptible to extinction and cue competition.

Conventional descriptions of classical conditioning emphasize the development of CRs to the CS. However, numerous studies have shown that conditioning also alters how organisms react to, and interact with, the US. This expands the definition of classical conditioning to not only the way organisms represent their world but also a functional process through which animals increase their chances of survival and procreation (Hollis 1997).

## Applications Outside of the Laboratory

The study of classical conditioning has been, and still is, relevant for the development and improvement of applications outside of the laboratory. This section lists and describes some of these applications in the area of Psychopathology and Psychotherapy.

Experimental neuroses in dogs and humans: Applications of classical conditioning began to be developed shortly after Pavlov's initial demonstrations of conditioning (Pavlov 1927). One of Pavlov's collaborators, Shenger-Krestinikova, is cited as the first one who examined the so-called *experimental neurosis* in dogs. Shenger-Krestinikova implemented a task in which a dog had to discriminate between two different visual cues (i.e., a circle and an ellipse), one of which was followed by food. Once the discrimination was established, indicated by the animal salivating to the circle but not to the ellipse, both stimuli were gradually made more similar. The dog discriminated successfully between both visual cues until they were practically indistinguishable, at which point the animal showed responses not displayed previously which were, according to the researchers, indicative of emotional distress or akin to neurotic behavior.

Nikolai Krasnogorski, another of Pavlov's collaborators, extended this research to human subjects with a task based on that of Shenger-Krestinikova. In his study, a 6-year-old child had

to learn discrimination between two different auditory stimuli, which were then progressively made more similar to make the discrimination more difficult. Both experiments are considered as the first ones establishing that classical conditioning could be behind the acquisition of both adaptive and nonadaptive emotional responses to novel stimuli. These results were solidified and extended by the following research.

Acquisition and elimination of fear: The next step was performed by John B. Watson, an American psychologist and founder of behaviorism. Watson conducted research aimed to demonstrate how principles of classical conditioning could explain the acquisition and elimination of fear to different objects. In what is perhaps the most known and infamous experiment in the history of Psychology, he and his assistant Rosalie Rayner (Watson and Rayner 1920) conditioned an 11-month-old child called "little Albert" by pairing a white rat, to which Albert showed previously no fear, with the sound produced by clanging iron rods behind Albert's head. After several pairings, Watson and Rayner presented the rat by itself, to which the boy showed fear. Afterwards they examined whether fear could generalize to other objects by showing Albert a rabbit, a dog, and a fur coat, to which Albert also reacted with fear. Unfortunately, Watson and Rayner never had the opportunity to treat Albert's newly acquired fear, but an attempt in this direction was made in a subsequent experiment with a child called Peter. This child showed fear to white rats and rabbits, probably by means of conditioning during his life. Mary Cover Jones (Jones 1924), developed a procedure to reduce Peter's fear by exposing the child to the fear-eliciting objects in what they called "direct conditioning." Peter was put in a chair and given a snack while in parallel a white rabbit in a cage was put on the table in a distance that did not disturb the child. The procedure was repeated the next days with the rabbit slightly closer each time, until Peter could eat with the rabbit next to him, and even while playing with it. This method is similar to the procedure of counterconditioning described previously and constitutes the bases for the development of systematic desensitization.

Systematic desensitization: Pavlov's and Watson's research showed that problematic behaviors such as fear could be explained by classical conditioning. Jones' experiment with Peter also showed that fear could be eliminated by gradual exposure to the fear-eliciting stimuli. This last result was further developed and systematized by the work of Joseph Wolpe. Wolpe, a South African psychiatrist, developed a model for the acquisition and treatment of fear and anxiety that was based on his previous work with cats as subjects. In his experimental work, cats received pairings of an auditory cue with a foot shock in an experimental chamber. After a few pairings, cats acquired fear to the auditory stimulus, which also generalized to the experimental cage. According to Wolpe's report, mere exposure (i.e., extinction) to the experimental cage failed in reducing fear responses, and thus he evaluated whether a response contrary to fear was more effective in decreasing it than exposure alone. Cats were gradually exposed and fed in situations more and more similar to the fear-inducing cage until the animals managed to eat in the experimental cage. A similar approach was used to eliminate fear to the auditory cue.

Based on these findings, Wolpe suggested the same manipulation could be used to reduce fear and anxiety in human patients. Although the procedure was first developed by Watson y Jones, it was Wolpe who systematized and published the steps of what he termed "systematic desensitization" (henceforth SD; Wolpe 1961). Wolpe based the treatment on what he called "reciprocal inhibition," the idea that anxiety could be "inhibited" by inducing an incompatible emotional state. As designed by Wolpe, a typical SD procedure has three steps:

(a) Establish a hierarchy of anxiety-related stimuli: The therapist and the patient identify the objects or stimuli that are associated with anxiety. Each item is given a rating based on the level of anxiety it provokes; (b) Train an incompatible response: The most used incompatible response is relaxation training such as meditation or breathing exercises. Patient are taught these strategies as a way to counteract the anxiety; (c) Exposure to the anxiety-related stimuli: While in the relaxed state,

the patient is gradually exposed to the anxiety-eliciting items beginning with the object with the lowest level in the scale developed in Step 1 until the patient reports no fear. Afterwards, the patient is exposed progressively to the next items in the anxiety scale. Wolpe's initial reports were followed by numerous publications showing the effectiveness of SD on a variety of disorders.

Exposure therapy: Although Wolpe's work is commonly described as one of the beginnings of exposure therapy, the basic principles are different as systematic desensitization is based on the counterconditioning procedure while exposure therapy is based on extinction, and as such does not necessarily involve the previous induction of an incompatible state. Exposure therapy is a type of cognitive-behavioral therapy in which the patient is confronted with the stimulus or event that is associated with the problematic behavior (hence the name). For example, an exposure-based approach for a phobia to spiders will involve exposing the patient, gradually or otherwise, to pictures of or real spiders until the phobic symptoms recede.

Exposure treatments have several variations depending on the procedure. On the one hand, exposure can be graded as in systematic desensitization or can begin with the stimulus with the highest anxiety level, in a procedure known as *flooding*. Exposure itself can be conducted in vivo, that is, in direct presence of the problematic object. For example, a patient with social anxiety might be instructed to give a speech to an audience. *Imaginal exposure*, on the other hand, involves instructing the patient to imagine vividly the object or situation. This is particularly useful when the anxiety-eliciting events are not available as, for example, with patients with post-traumatic stress disorder. In the last years, *virtual reality* exposure has become more common with the development of technology.

Research has shown that cognitive-behavioral therapy, and especially exposure therapy, is effective in alleviating the symptomatology of many disorders, including but not limited to phobias, PTSD, OCD, and reactivity to drug and food-related cues.

Relapse and prevention of relapse: As mentioned before, the effect of experimental extinction

is frequently temporary, and the extinguished response can recover. In the same manner, exposure therapy does not destroy the potential of the phobic object to cause the problematic response. Thus, the circumstances under which the extinguished response recovers have served as a model for the study of relapse in exposure therapy and its prevention. Relapse occurs frequently when the patient has experience with the aversive event outside of the treatment context (renewal), and when some time has passed since the last exposure session (spontaneous recovery).

Basic research has showed that some manipulations have potential to prevent relapse. One of them is massive extinction. In animal studies, it refers to the amount of extinction trials received by the subjects, which can go up to ten times the number of trials received by a control group. The results have showed that massive exposure is successful in attenuating and even completely preventing relapse, although so far it has only been examined in specific experimental preparations. A second treatment is conducting exposure in many contexts as opposed to in one. Several studies have reported in different experimental preparations that exposure in multiple contexts attenuates relapse, although its effectiveness might be qualified by several factors, such as the number of contexts in which fear was acquired, or the similarity between the exposure and/or acquisition contexts. Another technique is the use of extinction cues or retrieval cues for extinction. An extinction cue is a stimulus that is presented during exposure and then is used after it is over. Extinction cues have been shown to attenuate relapse in both animal and human studies, and with different experimental preparations. Finally, a less investigated treatment is what in the animal studies is called “deepened extinction.” In this manipulation, the patient is exposed simultaneously to multiple anxiety-eliciting cues. This is supposed to produce a better extinction (i.e., reduction in reactivity to cues) than exposure to a single cue. Some studies have shown in both animals and humans that deepened extinction successfully prevents relapse caused by the passage of time (spontaneous recovery) and by the presentation of an aversive stimulus (reinstatement).

## Current Status of the Study of Classical Conditioning

The principles of classical conditioning are related to many areas of Psychology, but their study by neuroscientist has been prolific in continuously showing the potential neural correlates to different phenomena of classical conditioning.

Several research suggested relationships between phenomena previously described here like blocking, conditioned inhibition, and extinction and the activity of the brain. Furthermore, neuroscience also has shown some evidence that relates the activity of the brain with specific theories of conditioning. One example of this evidence is the relationship between dopaminergic and norepinephrinergic activity and error correction. Structures like the basal ganglia, the cerebellum, and striatum among others appear to be involved in predicting rewards and subsequent behavior (Schultz and Dickinson 2000).

Many neuroscientists that work on areas related to the neural bases of learning choose to work on classical conditioning because it has been extensively researched and it provides with simple yet useful learning situations to analyze.

Likewise, classical conditioning is closely related to cognitive Psychology. As suggested above, many theorists of learning have stated that perception, attention, and other basic processes affect how we learn about the environment. Furthermore, a particular approach to cognitive processes called “connectionism” often uses a principle called “delta rule” that closely resembles Rescorla-Wagner’s rule for error correction. These models understand various cognitive phenomena through multiple parallel associations between inputs (stimulus) and outputs (response), which bear many similarities with the principles of classical conditioning.

All these links between classical conditioning and other areas of research, together with the continuously growing clinical application that have come from the study of classical conditioning, show that this is still a very active area. Moreover, the theories of the mechanism behind classical conditioning are still being updated and becoming more and more complex in a continuous rate.

## Definition

Curved bone of the shoulder (pectoral) girdle that typically serves to link the shoulder blade (scapula) and breastbone (sternum) in vertebrates.

## Introduction

The term “clavicle” originates from the Latin word *clavicular*, meaning little key. This describes the function of this bone in that it rotates along its axis similar to a key when the shoulder is abducted (rotated away from the body). When present, this bone serves as a strut to support the shoulder. It is in fact the only long bone, meaning a bone longer than it is wide, of the body that is oriented in a horizontal fashion (Nagashima et al. 2016). Clavicles are present in most mammals with prehensile forelimbs, but they are absent in sea mammals and animals that have evolved to be more adapted for running. The furcular bone, more commonly known as the wishbone in birds, is composed of two clavicles fused together (Larson 2009). Aside from species variations, there are several other characteristics of clavicles that make them unique.

## Classification of Organisms

## Synonyms

Collarbone

## Anatomy

The shoulder joint is comprised of both the clavicle and the shoulder blade. Humans have two clavicles that reside on either side of the bottom of their neck. Clavicles are essentially s-shaped rods that articulate laterally with the outer end of the shoulder blade that form the shoulder joint. They articulate on the midline with the breastbone or sternum. The degree of muscling of an individual can dictate the robustness of the clavicle. The clavicles serve as attachment points for numerous muscles (Nagashima et al. 2016).

## Function

The clavicle allows rigid support of the shoulder blade, leading to the ability for the limb to be

freely suspended. This gives the arm maximum range of motion and flexibility. Protected by the clavicles, there are also nerves and vessels going to the limb that run along and underneath the clavicles. Physical impacts can be transmitted from the upper limb to the core skeleton by way of the clavicles. The clavicle also serves as an attachment for several important muscles including deltoid, trapezius, pectorals, sternohyoid, and the subclavius that are crucial in movement and stabilization of the arm (Voisin 2006).

### Species or Sex Variation

In some mammals requiring greater freedom of motion, clavicles have become reduced or absent, allowing these animals the ability to run faster. Birds use their fused clavicles, termed wishbones, to strengthen their chest to withstand the harsh forces of flight. In most cartilaginous and bony fish of today, clavicles are absent, but in primitive bony fish, the clavicles were associated with the pectoral fin and were located just behind and below the gills on each side. On the fish's underside, there was a solid connection of the two, termed a symphysis (Larson 2009). In human females, clavicles are characteristically shorter, lighter, thinner, smoother, and less curved when compared to males. These classic distinct differences can be utilized in the sex determination of a human skeleton. (Larson 2009)

### Development of the Clavicle

During the development of a human embryo, the clavicle is interestingly the first bone to begin the process of ossification, essentially meaning the laying down of minerals onto a matrix that was preformed, yet it is one of the last bones to finish ossification. This process starts at approximately 5–6 weeks of gestation and is complete by 21–25 years of age. (Larson 2009) Unlike other long bones, the clavicle is thought to not have a medullary cavity, the site where the bone marrow is housed. Another unique characteristic of the clavicle is that it forms from two separate

ossification centers. The outside or lateral end of the clavicle undergoes intramembranous ossification, while the end near the midline undergoes endochondral ossification (Voisin 2006). This means that there is development of the bone via replacement of connective tissue and replacement of a cartilage matrix, respectively.

A unique congenital condition in which the clavicles are absent or imperfectly developed in humans is termed Cleidocranial dysostosis. This occurs in approximately 1 out of 1,000,000 people globally, resulting in drooping of the shoulders and the ability of the shoulder blades to meet at midline. It is thought to be associated with the RUNX2 gene that codes for transcription factor protein that is in charge of the regulation of the bone forming cells, osteoblasts (Larson 2009). There are an array of other abnormalities associated with the condition, in particular delayed ossification of the skull leading to the sinuses being underdeveloped and an open fontanelle.

### Traumatic Injury to the Clavicle

Many are familiar with broken collarbones as the result of injury or trauma. The S-shape of the bone allows for fractures to occur at the angle of greatest change in its direction. A fractured clavicle results in the sternocleidomastoid muscle lifting from the medial aspect, ultimately causing puncture of the overlying skin (Voisin 2006). Causes of clavicular fractures occur when a person falls either horizontally onto the shoulder or with an outstretched hand attempting to catch themselves. There is a transmission of forces from the core or axial skeleton onto the bone with a greater force than the strength of the clavicle. When a fracture of the clavicle occurs, it results in the trapezius muscle not being able to support the weight of the arm. This leads to the characteristic broken collarbone image of a man supporting his arm with the opposite hand. Because the clavicle is directly under the skin and is not covered with muscle, fractures can easily be felt and even seen. Interestingly, the clavicle is the most commonly injured bone of childhood, accounting for 10% of all fractures (Voisin 2006). Fractures to the shaft of the clavicle can be

managed without surgery by giving the arm a short (approximately 2 weeks) rest in a sling. Uncommonly, dislocation of the clavicles occur but are often related to contact sport injuries.

## Conclusion

The clavicle, or collarbone as more commonly known, is a bone not present in all species. It has become vestigial in some animals or completely absent in others. It is one of the most commonly broken human bones and is home to several important muscle attachments responsible for muscular structure and support of the arm. Though it is one of the first bones to begin ossification, it is one of the last to become completely ossified.

## Clever Hans

Juan M. Rosas  
Universidad de Jaén, Jaén, Spain

## Definition

Hans was a famous German Orlov Trotter horse trained by his owner, Wilhelm von Osten, who claimed that the horse was able to perform a variety of cognitive tasks, including solving

complex arithmetic operations, giving the time, showing knowledge about calendar dates, understanding German language, and so on. His ability aroused worldwide interest at the beginning of the twentieth century, gaining the appellation of Clever Hans (der Kluge Hans in German). Experimental research conducted by the psychologist Oskar Pfungst found that the horse had no particularly complex cognitive abilities, although he was extremely skilled at gathering and using information from the most subtle movements of the questioners to give the expected response. This effect, later known as the observer-expectancy effect, shows the importance of keeping a tight control in experimental research using whenever possible an automated presentation of stimulation and recording of responses and, whenever that is not possible, using what is called the double-blind experimental design in which neither the experimenter nor the subject knows what behavior is expected from the subject.

## Introduction

Wilhelm von Osten taught mathematics at a German gymnasium during the early twentieth century, and he was the proud owner of a Russian trotting horse. He tutored the horse for 4 years, teaching him how to solve complex arithmetic problems by means of tapping with his feet. Exhibition of the ability of the horse, named Hans, was given daily in a courtyard in the northern area of Berlin. No fee was ever charged for attending to the exhibition as the owner, W. von Osten, was convinced that he had developed a training method that would allow showing that the difference between animal and human minds was a question of degree rather than quality. The horse Hans was able to answer a variety of questions by tapping with his front legs, like the number of people in the audience wearing hats or the result of adding two fractions such as  $2/5 + 1/2$  by tapping first the numerator and then the denominator (9/10). He was claimed to master cardinal numbers up to 100 and ordinals at least up to 10. He was also claimed to be able to read in German, bring a piece of a particular color from a row of colored cloths, tell the time to the minute,

recognize notes and music intervals, and select which tones should be eliminated in a sequence of notes to reach a pleasant sound. Hans seem to be the living proof of Darwin (1871, p. 85) assertion: “Nevertheless the difference in mind between man and the higher animals, great as it is, certainly is one of the degree and not of kind.”

The ability of Hans, the horse, was uncanny, and he was classified by experienced educators as having the cognitive development of a 13–14-year-old teenager. Goes without saying that the interest about this particular horse spread rapidly throughout the world leading to a flood of articles in newspapers and magazines, being one of the most cited the one published on October 2, 1904, in the *New York Times*, in which it was lightly concluded that an special commission of experts decided that the horse actually used the reason. The image of the horse appeared in postcards, liquor labels, and other commercial products. Men of the greatest knowledge and reputation, of unimpeachable honor, would approach skeptical to the horse abilities, leaving convinced that they were truthful. The respected zoologist and African traveler, C. G. Schillings, was convinced by the fact that the horse was able to respond to strangers in the master’s absence, assuring that they have not made the slightest sign to guide Hans response. Spectators were counted by the thousand, and they included from trick trainers to horse fanciers, but none of them was able to discover any kind of signals that the owner could be given to the horse to solve the problems. The issue was taken so seriously that Professor Carl Stumpf, the director of the Psychological Institute of the University of Berlin, after a cursory inspection during the month of February, 1904, requested from Mr. von Osten in July to detail the method he used to instruct the horse, before finally recommending the appointment of an investigating commission on September 3, 1904.

### Von Osten’s Training Method

The method used by Mr. von Osten to train the horse was indeed quite simple and resembles the behavioral shaping method described by Skinner (1951) years later as a method of training by which

successive approximations toward a target behavior are reinforced. W. von Osten conducted arithmetic training by using different sets of wooden pins, a counting machine (abacus), a chart upon which were pasted the numbers from 1 to 100, and digits cut in brass and suspended from a string. Pieces of bread and carrots were used as rewards.

The work started by placing a single wooden pin in front to the horse and commanding him: “Raise the foot, one!” while holding the animal foot to ensure that the horse was giving only one tap. Once “one” was learned, he used two pins and the same method to train “two” and the rest of numbers. Gradually, it was not necessary to hold the foot, or to point to the pins, using directly the question “how many pins are there?” and associating the numbers with the responses. Once Hans allegedly learned the numbers, the next step was to teach the animal de concept “and,” that is, to teach the animal how to add. To teach the horse the concept of “and,” von Osten would have somebody holding a large cloth before the horse, where the wooden pins usually were placed. The cloth would be then taken up while pronouncing emphatically the word “and.” After this he would hide two of the pins behind the cloth. As a result of its previous instruction Hans would give two taps at the sight of the pins. The same procedure was repeated with three pins. The next step was to set five pins up, three of which were covered by the cloth. The horse would tap two times and von Osten would say “two.” The cloth then will be raised, Hans will give three taps more, and the trainer will say with emphasis: “and three.” The idea underlying this method was that the image of the five pins would be associated by the horse with the combined groups of two and three. The next step was to ask the question without aids, so that it could be shown that the horse had learned to add. The problems become gradually more complicated until Hans began to give solutions to new problems by himself, leading the master to believe that “he had succeed in inculcating the inner meaning of the number concepts and not merely an external association of memory images with certain movement responses” (Pfungst 1907/1911, p. 249).

Multiplication was taught to Hans by using the abacus. Von Osten would place two identical sets of balls (i.e., three balls), one in each extreme of the abacus, and would ask the horse for how many

times three balls were there, expecting two taps, then asking “how many, therefore are two times three?” Six taps. The horse was supposed to learn the meaning of the word “times” by means of the spatial separation of the groups, counting the number of groups and the number of balls in each group. Subtraction was taught by setting a given number of pins up (i.e., five), removing some of them (i.e., two) while saying emphatically “I take away, two minus. How many are still standing?” A similar procedure was used for division and for other arithmetic operations.

### The Hans-Commission

Following the recommendation of Professor Stumpf, a commission of 13 people was established with the goal of evaluating whether there was “involved in the feats of the horse of Mr. von Osten anything of the nature of tricks, that is, intentional influence or aid on the part of the questioner” (Pfungst 1907/1911, p. 117). The commission involved a variety of relevant people, including a circus manager, members of schoolboards, directors of Berlin Zoological Garden, physiologists, and the director of the Psychological Institute of Berlin and member of the Academy of Sciences, Professor Carl Stumpf.

The commission conducted a large number of tests in the two sessions that took place on the 11th and the 12th of September, 1904, trying to search for the trick that could explain the behavior of the horse. In many of those tests, von Osten was not present but on September 12, 1904 two sets of experiments were conducted in which von Osten was present in the set. In the first set of experiments, a different man questioned the horse, while von Osten was present, but outside Hans’s view. The first set of questions was solved by Hans with little errors. In the second set of questions there was another man, the Zoologist and African traveler, C. G. Schillings, whom asked the horse to tap a certain number in the absence of von Osten, left the set, and then the owner entered the room and asked the horse to perform some arithmetical operation with a number that he was not aware of which one it was. In those tests, the horse did

not perform near as well as in the other. In most tests, the horse repeated the original number, rather than the operation he was asked to perform. However, there was a misunderstanding that lead Schillings to say to the horse “you are to repeat this number for Mr. von Osten” in the first few trials so that the errors might appear to be the result of this request or at least left the possibility open for an inconclusive test.

After its careful investigation, on their report of September 12, 1904, taking in account the individual experiences of the members of the commission with the horse, the report provided by Professor Stumpf on the method of instruction, and the two sessions of exploration, the commission concluded that no tricks or aids of the traditional sort were being employed by Hans’s owner. In their report it is said “In spite of the most attentive observation, nothing in the way of movements or other forms of expression which might have served as a sign, could be discovered. (. . .) They are unanimously agreed that this much is certain: This is a case which appears in principle to differ from any hitherto discovered, and has nothing in common with training, in the usual sense of that word, and therefore is worthy of a serious and incisive investigation” (Pfungst 1907/1911, pp. 253–254). Not quite the conclusion that the press at the time actually published, but one that opened the door a further and more controlled research that was finally conducted by the psychologists O. Pfungst.

### Oskar Pfungst’s Study on Hans Accomplishments

Given that no usual trick was discovered by the commission, and following the recommendation of conducting a more incisive research about the abilities of clever Hans, Oskar Pfungst conducted a careful set of experiments with the goal of discovering the actual abilities of the horse. The experiments were conducted in the courtyard of the owner, and most of them were conducted by Pfungst himself, using carrot, bread, and occasionally a square of sugar as rewards.

O. Pfungst approached the research by using what he called two different procedures. The so-called procedure without knowledge was a procedure in which neither the questioner, not anybody in the audience knew the answer to the question the animal was asked, for opposition to the procedure with knowledge, in which the questioner knew the answer to the problem. Applying these procedures to problems that could be solved by tapping involving numbers in cards, words in placards, computation, counting using the abacus, memory tests, calendar dates, and musical abilities, Pfungst (1907/1911) found that the mean percentage of correct responses in the procedure without knowledge was about 10%, while in the procedure with knowledge was about 90%. Auditory stimuli seem not to play a role, as the animal could not follow instructions given by a questioner that was hidden from the horse's sight by blinders. Similar results were obtained in those problems that Hans solved with movements of the head and in those that were solved by approaching objects.

As the horse failed to find the solution when that solution was unknown by the people present, and the horse needed to see the questioner to give a solution, it was concluded that the horse was using some aid that was unintentionally given by the questioner. Focusing the exploration in the questioner, Pfungst (1907/1911) found that the horse behavior was controlled by minimal movements of the head and trunk of the questioner. A slight bent of the head while leaning the trunk slightly forward made the horse begin to tap with his right foot. As soon as the horse reached the right number of taps, the questioner would make a slight upward jerk of the head and the horse will stop tapping. Once these movements were isolated, Oskar Pfungst reports that he was able to control horse's behavior voluntarily, so that the horse will start tapping and stop tapping whenever the proper movements were given by the Pfungst, regardless of the question asked. In fact, he was able to control the rate of tapping by varying the angle of the inclination of the body so that greater the inclination, the faster the tapping.

The conclusion was clear "All wonderful feats of counting and computation which were

accomplished while thus experimenting with the horse are to be accredited, not to the horse, but to the questioner (...) Hans, however, was also a faithful mirror of all the errors of the questioner" (Pfungst 1907/1911, p. 142). The results of this study were reported by Carl Stumpf on December 9, 1904, in which he says "The horse must have learned, in the course of the long period of problem-solving, to attend ever more closely, while tapping, to the slight changes in bodily posture with which the master unconsciously accompanied the steps of his own thought-processes, and to use these as closing signals. The motive for this direction and straining of attention was the regular reward in the form of carrots and bread, which attended it." This last statement seems a clear description of the role of discriminative stimuli in instrumental or operant conditioning, indeed.

## Conclusion

There are some essential lessons that any person interested in animal cognition and in science in general may learn from the story of Clever Hans. The first and perhaps the most obvious one is the need of applying the principle of parsimony or Morgan's Canon in any study of animal behavior: "In no case is an animal activity to be interpreted in terms of higher psychological processes, if it can be fairly interpreted in terms of processes which stand lower in the scale of psychological evolution and development" (Morgan 1895/1903, p. 59). In many occasions we tend to anthropomorphize the animal, providing it with feelings and abilities that are essentially human. It is true that we humans might tend to do the contrary at the same time, rejecting the idea that animals may have abilities that traditionally have been thought human exclusive. In that sense, it is convenient to remember that Lloyd Morgan himself completed his principle with a sentence that is often ignored by saying that "To this, however, it should be added, lest the range of the principle be misunderstood, that the canon by no means excludes the interpretation of a particular activity in terms of the higher processes, if we already have independent evidence of the occurrence of these

higher processes in the animal under observation” (Morgan 1895/1903, p. 59). This was not the case of Clever Hans, whom followed one of the perhaps more interesting features of evolution, the ability to find simple solutions for complex problems. Using the available stimuli unconsciously provided by the caretaker as discriminative stimuli for when an operant behavior would be followed by a reward was the simplest and most efficient and straightforward solution for a set of complex problems.

The second lesson that may be learned from the story of Clever Hans perhaps is not so obvious. An interesting question that is not usually raised is what led people of the beginning of the twentieth century to take so much trouble to study Hans’s behavior. Even when the so-called Hans commission concluded that there were no obvious tricks of any sort in von Osten’s behavior, the research was taken a step forward, and a systematic study was pursued. Of course, that is the way it should be done. But the question is would such a in-deep study have been conducted if there were not being a preconception about the (lack of) ability of the horse? In other words, would the same question had been applied when considering an ability that would fit the preconceptions about the species, regardless of whether they are true or not? These questions have no other goal than highlighting the need of applying Morgan’s cannon to any situation, regardless of the species involved, keeping in mind that solving a problem by simple means does not necessarily imply that the species is not able of more complex cognition but simply that the animal is not applying it to solve that specific problem.

Third, as stated above, the story of Clever Hans makes it evident the importance of using proper controls when studying cognition regardless of the species to avoid the observer-expectancy effect, an effect in which the experimenter unconsciously influences behavior of the participant in a given experiment. This effect is usually controlled by using automatic recordings of behavior and by the use of the double-blind experimental design in which neither the experimenter nor the participant know the condition in which the participant are, not the behavior it is expected from him or her. This was essentially the method used O. Pfungst to explore Hans cognitive allegedly abilities.

Finally, the way the story of Clever Hans one may tend to question whether the horse actually deserved his nickname. When the research conducted by O. Pfungst showed that Hans did not have the abilities his master ascribed to him, Von Osten was both puzzled and deceived, showing a reaction that was described by O. Stumpf as “genuine surprise, such a tragicomic rage directed against the horse” (Pfungst 1907/1911, p. 13), and explicitly forbid to conduct further experiments with him. It is easy to understand and even to share von Osten’s disappointment. However, the story may be seen from a different point of view. In the story of Clever Hans, it is implicitly assumed that the problems the horse had to face were complex cognitive problems. But let’s put ourselves in the horse’s shoes. The only problem Hans had to solve was how to get the piece of carrot that his master provided when he tapped the right number of times. The key of the solution was the rule that determined which number was right. Von Osten established a complex set of rules for determining the correct number of tapings consciously and just one unconsciously. This latter one was the one used by Clever Hans. It was so subtle that a commission formed by 13 intelligent, motivated, and highly trained people was not able to discover the rule after two days searching for it. No wonder that Hans has kept the appellation of “clever” over a century.

## Clive Wynne

Clive D. L. Wynne

Arizona State University, Tempe, AZ, USA

Clive D. L. Wynne was born and grew up on the Isle of Wight, an island, 25 by 15 miles, off the south coast of England. After completing high school there, in 1980, he went to University College London to study *Human Sciences*. Human Sciences is a degree program, founded by anatomist J. Z. Young, that introduces students to all the sciences that contribute to understanding the human condition. It was at University College that Wynne was first exposed to the ideas that have influenced his thinking ever since. In classes with pioneer evolutionary psychologist, Henry Plotkin, Wynne learned that the evolutionary process of natural selection can be construed as a learning process. As organisms adapt to the world around them, they are in effect gaining knowledge of the world. Plotkin and Odling-Smee (1979; Odling-Smee and Plotkin 1984) argued that there were multiple levels at which the biological world learns about the physical world, ranging from the adaptation of organisms through natural selection as usually construed, to the individual learning of animals interacting with their environment, and even the interaction of societies. Concurrently Wynne was taking classes in epistemology from Nicholas Maxwell (e.g., Maxwell 1984). In these classes, Wynne learned about Popperian epistemology: the idea that people learn by repeatedly testing hypotheses about the nature of the world (Popper 1974). Maxwell and Plotkin explicitly drew parallels between the way that individuals learn by testing hypotheses and the way that nature “learns” by “testing” individual variations which are selected by nature. Together with classes on what was known about how animals learn, this intellectually stimulating education set the basis for much of Wynne’s subsequent research career.

From University College London, in 1984, Wynne went to Edinburgh University for his PhD. Initially he was mentored by Brendan

McGonigle, and later by Peter Caryl. McGonigle exposed Wynne for the first time to cutting edge research in animal cognition, and Caryl started Wynne’s education in classical ethology.

From Edinburgh, in 1986 Wynne applied to join John Staddon’s lab at Duke University, North Carolina, as a postdoc. Staddon, however, was on sabbatical at the University of the Ruhr, in Bochum, Germany, with Juan Delius that year, so Wynne joined Staddon there. The juxtaposition of Staddon and Delius was a very advantageous one for Wynne’s continuing education. From Staddon, Wynne learned about operant conditioning; and from Delius he learned more about ethology. Both Staddon and Delius were committed to reconciling the operant and ethological approaches within a biological, evolutionary framework – and Wynne absorbed this perspective readily.

Over the next several years, Wynne was a postdoctoral associate with Staddon at Duke University and with Delius in Bochum and later at Konstanz University in southern Germany. During this time, Wynne deepened his knowledge of operant conditioning, ethological approaches to animal behavior, animal cognition, and, thanks to Peter Holland at Duke and John Pearce from Cardiff University, on sabbatical at Duke while Wynne was there, Pavlovian conditioning.

By the time Wynne found his first faculty position, in 1993, at the University of Western Australia, in Perth, Australia, he had established two lines of research. The first concerned how pigeons adapt to changes in temporal regularities in their environment (e.g., Wynne et al. 1996), and the second an investigation of the basic behavioral mechanisms that make it possible for pigeons to achieve the apparently highly complex form of deductive reasoning known as “transitive inference” (e.g., Wynne et al. 1992; Wynne 1997)

In Australia Wynne was also able to develop simple tests of behavioral adaptation in two species of marsupials. From the little research that had been carried out, marsupials had a reputation for low intelligence. Wynne was able to show that one marsupial, the Fat-tailed Dunnart (*Sminthopsis crassicaudata*) which occupied a niche somewhat similar to a field mouse, was

in fact one of the fastest learners ever tested (Bonney and Wynne 2002a). A second marsupial species, the quokka (*Setonix brachyurus*) was a slower learner (Bonney and Wynne 2002b). Comparison of these two species showed that animals have the learning capacities that their lifestyles require of them.

From the University of Western Australia, Wynne moved to the University of Florida, in Gainesville, Florida in 2002. Here he continued research on the ability to time short intervals in pigeons (e.g., McClure et al. 2005), but found he was also very interested in the relationship between people and animals. In 2004 he published a review on the research that had been published, starting in the late 1990s, on the behavior of dogs in interaction with humans (Wynne 2004). This led to the realization that dogs would be an ideal species of study in which to combine his established expertise in animal behavior and cognition with a growing interest in human-animal interaction. It also connected with Wynne's childhood love of dogs.

At first, Wynne's dog research focused on the nature and limits of dogs' understanding of human actions and intentions, particularly in comparison to dogs' wild progenitor, the wolf (*Canis lupus lupus*; e.g., Udell et al. 2008, 2010, 2011). More recently, his research has broadened to include studies of the welfare of dogs living in shelters (e.g., Protopopova et al. 2012; Protopopova and Wynne 2015), behavior-analytic approaches to dog behavioral problems (e.g., Protopopova et al. 2014), novel methods of training Improvised Explosive Device detection dogs (e.g., Hall et al. 2015a, b), alongside basic questions of behavior and cognition in dogs (e.g., Feuerbacher and Wynne 2012; Udell et al. 2012). He also maintains an interest in the archeological and genetic studies contributing to our understanding of the origins of dogs. In 2013, Wynne moved to Arizona State University where he continues to study diverse aspects of dog behavior. Wynne's future research is likely to continue to focus on dogs and their wild relatives in interaction with human beings. He seeks to find the "pointy end" of dogs' lives with humans – those areas where most is at stake

for people and their pets. At the same time, he still strives to understand how evolution has been able to make animals like dogs which have adapted to a radically changed, anthropogenic, niche in what is evolutionarily speaking, a very brief interval of time.

## Clutch

Amanda M. Dettmer  
Laboratory of Comparative Ethology, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, USA

---

## Definition

A clutch refers to the number of eggs in a nest laid in a single brood produced by oviparous (i.e., egg-laying) animals such as birds, amphibians, fish, or reptiles.

## Description

Clutch size varies greatly between species, and often within species due to variations in habitat, health, resource availability, predation pressures, and time of year (Klomp 1970). However, some species are determinant layers, laying a species-specific number of eggs. Long-lived species tend to have smaller clutch sizes, as do shorebirds and monogamous birds (Klomp 1970). Ornithologist and evolutionary biologist David Lack was a pioneer in the study of clutch size. His work in the 1940s (Lack 1947, 1948) explored intraspecific variation in clutch size (including latitude – increasing latitude results in increasing clutch size – island living, seasonal variation, annual variation, and age of bird), interspecific variation in clutch size (i.e., average clutch sizes in different habitats), and factors involved in clutch size (including physiological control, species mortality, and day length variation). Lack's work led him to hypothesize that natural selection has resulted in clutch sizes evolving toward a number that produces the most surviving offspring (Lack 1947, 1948), and that the mechanism determining the upper limit to clutch size is the parents' ability to provide food for nestlings (Lack 1954, 1966). However, more recent work has found that the evidence does not support Lack's clutch size hypothesis (Vander Werf 1992).

An alternate hypothesis to explain optimal clutch size is Skutch's hypothesis, which states that higher nest predation decreases the rate at which parents can deliver food to their nestlings, and thus limits clutch size (Skutch 1949), though few studies support this hypothesis. More support exists for Ashmole's hypothesis (Ashmole 1963), which explains the latitudinal difference in clutch sizes by differences in the seasonality of resources, which result in different levels of winter mortality (see Greibeler and Böhning-Gaese 2004; Ricklefs 1980), although other factors such as cost of reproduction (Greibeler and Böhning-Gaese 2004) must be considered as well.

Clutch size can be altered within a breeding season, both naturally and artificially. "Double-clutching," defined as an oviparous animal laying two sets of eggs in a viable season, can occur after

destruction of a first clutch by predators or by removal by humans (e.g., in the California condor breeding program). In the latter case, double-clutching is used to double the production of a species' eggs specifically to increase population size.

## Coalition Enforcement

Lorenzo Magnani

Department of Humanities, Philosophy  
Section and Computational Philosophy  
Laboratory, University of Pavia, Pavia, Italy

### Synonyms

Cooperation; Mutualism; Proto-social behavior;  
Social behavior

### Definition

Coalition enforcement relates to the affirmation of moral or proto-moral behavior and to the related perpetration of violent punishment, to the aim of preserving cooperation.

### Introduction

The aim of this entry is to clarify the idea of “coalition enforcement.” This idea illustrates a whole theoretical background for interpreting the role of morality and violence in human and in nonhuman animal groups. In this last case, it is useful to speak of the role played in coalitions of what we humans can call – anthropomorphically – “proto-moral conflicts.”

### Coalition Enforcement Hypothesis: Morality and Violence

The coalition enforcement hypothesis, put forward by Bingham (1999, 2000), aims at providing an explanation of the “human uniqueness” that is at the origin of human communication and language, in a strict relationship with the spectacular ecological dominance achieved by *H. sapiens*, and of the role of cultural heritage. From this perspective, and due to the related constant moral and policing dimension of *Homo*’s coalition enforcement history (which has an approximately

two-million-year evolutionary history), human beings can be fundamentally seen as *self-domesticated animals*. The main value of this hypothesis consists in stressing the role of the more or less stable stages of cooperation *through morality* (and through the related unavoidable violence generated by punishment).

The hypothesis implicitly shows how both *morality* and *violence* are strictly intertwined in their social and institutional aspects, which are implicit in the activity of cognitive niche construction. In an evolutionary dimension, coalition enforcement is enacted through the construction of social artefactual niches (recently called *cognitive niches* (Laland et al. 2000)) as a new way of diverse human adaptation. Basically the hypothesis refers to cooperation between related and unrelated animals to produce significant mutual benefits that exceed costs and are potentially adaptive for the cooperators. Coalition enforcement is active at both the human and nonhuman animal level:

1. Tomasello (2009) has usefully studied various types of human and animal altruism but also human cooperation through social institutions.
2. Wilson et al. (2004) hypothesized the role of groups in engaging in coordinated and cooperative cognitive processes, thus exceeding by far the possibilities of individual thinking, and emphasized the formation of the so-called group mind whose role would be fundamental in social cognition and group adaptation. The formation of appropriate groups which behave according to explicit and implicit more or less flexible rules of various types (also moral rules, of course) can be reinterpreted – beyond Wilson’s strict and puzzling “direct” Darwinian version – as the “social” constitution of a “cognitive niche,” that is, a cognitive modification of the environment which confronts the coevolutionary problem of varying selective pressures in an adaptive or maladaptive way. It is Pinker (2010) that deeply studied the coevolution of intelligence, sociality, and language in the perspective of cognitive niches (see also Magnani (2011)).

In hominids, cooperation in groups (which, contrary to the case of nonhuman animals, is largely independent from kinship) is fundamentally derived from the need to detect, control, and punish social parasites, who, for example, did not share the meat they hunted or partook of the food without joining the hunting party (Boehm 1999) (also variously referred to as free riders, defectors, and cheaters). These social parasites were variously dealt with by killing or injuring them (and also by killing cooperators who refused to punish them) *from a distance* using projectile and clubbing weapons. In this case injuring and killing are cooperative and remote (and at the same time they have to be seen as “cognitive” activities). According to the coalition enforcement hypothesis, the avoidance of proximal conflict reduces risks for the individuals (hence the importance of *remote killing*). Of course, cooperative morality that generates “violence” against unusually “violent” and aggressive free riders and parasites can be performed in other weaker ways, such as denying a future access to the resource, injuring a juvenile relative, gossiping to persecute dishonest communication and manipulative in-group behaviors or waging war against less cooperative groups, etc.

The development of the cooperative morality is related to the so-called Machiavellian intelligence hypothesis. Posed in the late 1980s (Whiten and Byrne 1988), the “social brain hypothesis” (also called “Machiavellian intelligence hypothesis”) holds that the relatively large brains of human beings and other primates reflect the computational demands of complex social systems and not only the need of processing information of ecological relevance: the ability to manipulate information and not simply to remember it, to recognize visual signals to identify other individuals, sufficient memory for face recognition and to remember who has a relationship with whom, use of tactical deception and coalition, ability to understand intentions, to hold false beliefs, “mind-reading,” known as “theory of mind,” etc. Language itself would have evolved from physical grooming as a way of creating social cohesion as the size and complexity of the social group increased (cf. also Dunbar (1998)).

In summary, group cooperation (e.g., for efficient collective hunting and meat sharing through control of free riders) has been able to evolve adaptively and to render parasitic strategies no longer systematically adaptive. Through cooperation and remote killing, individual costs of punishing are greatly reduced and so are individual aggressiveness and violence, perhaps because violence is morally “distributed” in a more sustainable way: “Consistent with this view, contemporary humans are unique among top predators in being relatively placid in dealing with unrelated conspecific nonmates under a wide variety of circumstances” (Bingham 1999, p. 140). Hence, it has to be said that humans, contrarily to nonhuman animals, exchange a fundamental and considerable amount of relatively reliable information with unrelated conspecifics (p. 144). Here the role of docility is worth citing (which relates to the distressing human tendency to conform, displace responsibility, comply, and submit to the authority of dominant individuals, also emphasized by social psychology).

### Docility and Moral Viscosity

According to Herbert Simon (1993, p. 156), humans are docile in the sense that their fitness is enhanced by “[...] the tendency to depend on suggestions, recommendations, persuasion, and information obtained through social channels as a major basis for choice.” In other words, humans support their limited decision-making capabilities, relying on external data obtained through their senses from their social environment. The social context gives them the main data filter, available to increase individual fitness. Therefore, docility is a kind of attitude or disposition underlying those activities of cognitive niche construction, which are related to the delegation and exploitation of ecological resources. That is, docility is an adaptive response to (or a consequence of) the increasing cognitive demand (or selective pressure) on those information-gaining ontogenetic processes, resulting from an intensive activity of niche construction. In other words, docility permits the inheritance of a large

amount of useful knowledge while lessening the costs related to (individual) learning.

In Simon's work, docility is related to the idea of *socializability* and to altruism in the sense that one cannot be altruistic if he or she is not docile. In this perspective, however, the most important concept is docility and not altruism, because docility is the cognitive condition of the possibility of the emergence of altruism. Moral altruism, at least in the light of the coalition enforcement hypothesis, can be correctly seen as a sub-product of – or at least intertwined with – the violent behavior needed to “morally” defend and enforce coalitions. Given the fact groups need to detect, control, and punish social parasites, which, for example, do not share meat (food as nutrient as hard to acquire), by killing or injuring them (and any cooperators who refuse to carry out punishment), to this aim they have to gain the cooperation of other potential punishers: docility plays a positive role.

Research on chimps' behavior shows that punishment can be seen as altruistic for the benefit of the other members of the group (and to the aim of changing the future actions of the individual being punished), often together with “the function of keeping the top ranking male, or coalition of males, at top, or preserving the troop-level macro-coalition that disproportionately serves the interests of those on top” (Rohwer 2007, p. 805). The last observation also explains how altruistic punishment can serve individual purposes (and so it can be captured by individual selection models): in chimps it reflects the desire to maintain status that is a new high position in the hierarchy. Rohwer's conclusion is that “certain behaviors that can be covered by the definition of altruistic punishment need not have arisen from group selection pressures [...] as the Sober and Wilson model assumes. Seen through the lens of the linear dominance hierarchy, it is reasonable to suspect that altruistic punishment may have originated primarily through individual selection pressures” (p. 803 and p. 810). The reader that is interested to further study the puzzling problem of the distinction between individual and group selection for altruism in the framework of multilevel selection has to refer to Rosas (2008): multilevel selection

theory claims that selection operates simultaneously on genes, organisms, and groups of organisms.

Moreover, Lahti and Weinstein (2005) further emphasize the evolutionary adaptive role of morality (and so of cooperation) as “group stability insurance”: the exigence of morality as group stability would explain the “viscosity” of basic aspects of the morality of a group and why morality is perceived as having an air of absolutism. Viscosity represents the tendency of moral beliefs to *stick* to their holder in spite of the changing contexts. Indeed, the concept of viscosity provides an explanation of the gap between the absolutism of morality and the empirical evidence that moral regulations are often infringed with no major consequences neither for the whole moral system nor for the very individual who performs the infractions.

## Coalition Enforcement and Language

Furthermore, the problem of docility is twofold. First, people delegate tasks of data acquisition to their experience, to external cultural resources, and to other individuals. Second, people generally put their trust in one another in order to learn. A big cerebral cortex, speech, rudimentary social settings, and primitive material culture furnished the conditions for the birth of the mind as a “universal machine” – to use Turing's expression. It is plausible to think that a big cortex can provide an evolutionary advantage only in the presence of a massive storage of meaningful information and knowledge on external supports that only a developed (even if small) community of human beings can possess. If high-level consciousness is considered as related to a high-level organization of the human cortex, its origins can be referred to the active role of environmental, social, linguistic, and cultural aspects. It is in this sense that docile interaction lies at the root of our social (and neurological) development. It is obvious that docility is related to the development of cultures, morality, and actual cultural availability and to the quality of cross-cultural relationships. Of course, the type of cultural dissemination and possible cultural

enhancements affect the chances that human collectives have to take advantage of docility and thus to potentially increase or decrease their fitness.

### **Cultural Heritage: Extragenetic Information, Morality, and Sense of Guilt**

The direct consequence of coalition enforcement in humans is the development and the central role of cultural heritage (morality and sense of guilt included). From this perspective, the long-lived and yet abstract human sense of guilt represents a psychological adaptation, anticipating an appraisal of a moral situation to avoid becoming a target of violent coalitional enforcement. It is necessary to stress that Darwinian processes are involved not only in the genetic domain but also (with a looser and lesser precision) in the additional cultural domain, through the selective pressure activated by modifications in the environment brought about by cognitive niche construction. According to the theory of cognitive niches, coercive human coalition as a fundamental cognitive niche constructed by humans becomes itself a major element of the selective environment and thus imposes new constraints (designed by *extragenetic information* on its members) (cf. Magnani (2009) and Magnani (2011)).

Some empirical evidence (presented by Bingham (2000)) seems to support the coalition enforcement hypothesis: fossils of *Homo* (but not of Australopithecines) show, on observation of skeletal adaptations, how selection developed an astonishing competence in humans relating to the controlled and violent use of projectile and clubbing weapons (bipedal locomotion, the development of *gluteus maximus* muscle and its capacity to produce rotational acceleration, etc.). The observed parallel increase in cranial volume can be related to the increased social cooperation based on the reception, use, and transmission of “extragenetic information.” Moreover, physiological, evolutionary, and obstetric constraints on brain size and structure indicate that humans can individually acquire a limited amount of extragenetical information, that consequently has to

be massively stored and kept available in the external environment.

Hence, a fundamental role in the evolution of “non”genetic information has to be hypothesized. Appropriately, coalition enforcement implies the emergence of novel extragenetic information, such as large-scale mutual information exchange as forms of communication between unrelated kin, including both linguistic and nonlinguistic aspects (visual representations, thought experiment, analogical reasoning, but also the kinds of cognition also nonhuman animals can get through emotions and other feelings). It is noteworthy that extragenetic information plays a fundamental role in terms of transmitted ideas (cultural/moral aspects), behavior, and other resources embedded in artifacts (ecological inheritance). It is easy to acknowledge that this information can be stored in human memory – in various ways, both at the level of long-lived neural structures that influence behavior, and at the level of external devices (cognitive niches), which are transmitted indefinitely and are thus potentially immortal – but also independently of small kinship groups. Moreover, transmission and selection of extragenetic information are at least partially independent of an organism’s biological reproduction.

### **Conclusion**

In summary, to illustrate coalition enforcement, it is important to show how moral norms, cooperation, and social dominance hierarchies can be accounted for from an evolutionary point of view. Recent research acknowledges the role of social dominance hierarchies in cooperative activities of human and nonhuman animals (like social mammals), also stressing the deontic importance of moral behavior and intertwined violent components.

Evidence from comparative, developmental, and cognitive psychological research also show how they shaped the evolution of the human mind and so of human social institutions. Pressures that derive from living in hierarchical groups shaped basic concept and cognitive devices (which are not interpreted as innate modules but instead as

favored by a kind of “biological preparedness,” a propensity to develop them in a combination of genetical and environmental circumstances). These concepts and cognitive devices are in turn related to the various stages of development of cognitive niches, crucial factors to survive in those hierarchic settings. They are:

1. Recognizing and reasoning transitively about dominance relations (making rank and kinship discriminations)
2. Fast-track learning of social norms (permissions, prohibitions, and obligations)
3. Detecting violations of social norms and codes – also called *deontic effect* (cheating and deceptions to flout social norms and to have better access to reproductive opportunities through monitoring reciprocal obligations based on resource sharing)
4. Reading intentions of others and so predicting their behavior, especially – again – to favor detection of violations (but also to allow compassion and social codes based on something other than social norms).

Furthermore, perceived violations were already studied as the most common cause of aggression in primate groups (Hall 1964): without a capacity for violation detection, high-ranking individuals cannot monopolize resources and maintain fruitful alliances and preserve the peace. However, especially in human collectives, violation detection is the most precious tool for ensuring that social norms (implicit and explicit) are honored thus facilitating social regulation and promoting the emergence of altruism as a stable strategy.

Finally, it is worth noting the richness of recent research on the role of coalition enforcement in social mammals, usefully illustrated by Smith (2014). Also relying on empirical research favored by new methodologies, such as the possibility to track through less and less invasive GPS technologies an ever-growing number of species, the evolutionary puzzle of cooperation is illustrated in the framework of *kin selection theory*: Smith analyzes and discusses costs, benefits, and the direct and indirect lifetime fitness of

cooperative breeding (also active in social insects), nepotism, social tolerance, and withheld aggression in coalition formation (and so in “social evolution”). The concerned species range from primates to ungulates, from cetaceans to carnivores, from marsupials to rodents and bats. The author also shows the available evidence confirming the existence of actual fitness consequences of sociality in mammalian species including baboons (*Papio cynocephalus*), house mice (*Mus domesticus*), laboratory rats (*Rattus norvegicus*), horses (*Equus caballus*), dolphins (*Tursiops aduncus*), rock hyraxes (*Procavia capensis*), yellow-bellied marmots (*Marmota flaviventris*), and, obviously, humans. The special case of the highly cooperative behavior of dolphins and cetaceans is described in the recent Whitehead and Rendell (2014).

et al. 2008; Bygott et al. 1979; Connor et al. 1992). These members cooperate to obtain access to reproductive partners. Frequently, it has the effect of increasing the reproductive success of at least one member of the coalition. However, not every member of the coalition may participate in reproduction.

## Examples

Coalitional mating behaviors have been observed in numerous species. For instance, groups of male chimpanzees (*Pan troglodytes*) in wild populations have been observed working together to capture females from opposing groups for reproductive purposes (e.g., Boesch et al. 2008; Manson and Wrangham 1991). These males will cooperate as a group to search for mating partners of another group to be taken either temporarily or permanently from their original groups. Interestingly, males cooperating in these groups may not have direct reproductive access to taken females (Boesch et al. 2008).

Similar to chimpanzees, male bottlenose dolphins (*Tursiops* sp.) are known to form coalitions of two to three males and to then confine the movements of females (Connor et al. 1992). These coalitions of males can remain constant for years. Females are typically observed being chased by the male coalition for capture attempts. Once confined, the period of control by the male coalition has been perceived to range from several minutes to 13 days. The males will cooperate to prevent the female's escape through herding and aggressive behaviors.

In another mammal species, male lions (*Panthera leo*) have been observed forming coalitions of two, three, or more lions (Bygott et al. 1979). Larger coalitions benefit through an increased capability to seize control of the female prides. In lions, it is crucial for male coalitions to maintain control of female prides for a prolonged period due to the prevalence of infanticide by newly dominating males. Strengthening this ability, males in larger coalitions have been observed acting as nonreproductive “helpers” (Packer et al. 1991).

## Coalitional Mating

Jordyn Truax  
Oakland University, Rochester, MI, USA

## Synonyms

Cooperative mating

## Introduction

Coalitional mating involves individuals forming coalitions that then attempt to reproduce with other members of their species (e.g., Boesch

## Conclusion

The practice where members of the same species form coalitions with a purpose of reproducing, coalitional mating, may occur in any number of species. Some species that exhibit this behavior have been described above, including chimpanzees, bottlenose dolphins, and lions. While generally increasing the reproductive success of at least one member, interestingly some members may assist without the benefit of reproduction, suggesting some other motivation.

representations of experiences in sensation, perception, conditioning, memory, anticipation, problem solving, language, and related cognitive systems.

## Introduction

**Coding** is the process of creating neural and cognitive representations of information gained from experiences. Coding is the basis for neural or cognitive representations of sensory, perceptual, or cognitive experiences. Coding may be described at different levels of analysis: molecular, synaptic, cellular, neural systems, behavioral, cognitive, functional, and so forth. Information received from sensory receptor systems, such as visual, auditory, and other receptor systems, is translated into neural activity that can be stored veridically or after additional cognitive processing. Lower-level codes may represent sensory/perceptual “features” whereas higher-level cognitive codes derived from processing lower-level neural codes can represent “objects” or “concepts.” The characteristics of the resulting neural activity are specific to the stimuli or objects and thus can represent those stimuli or objects. For example, when an animal encounters a food item, the animal might experience several characteristics of the item, including odor, taste, and appearance. The neural code or codes related to the experience may represent individual or multiple characteristics of the food item, including information from sensory, perceptual, and memory systems which may store codes related to past experiences with the food item.

## Coding in Sensation and Perception

Coding of sense-specific information involves several steps: experience of the actual stimulus characteristics, creation of neuronal codes or activation of previously stored neuronal codes representing that or similar previous experiences, and processing of coded information in decision-making. Examples of sensory coding have been identified in many species, from visual system coding in invertebrates such as the fruit fly

*Drosophila melanogaster* (Harris et al. 1976) to vertebrates.

## Coding in Pavlovian and Instrumental Conditioning

The very idea of “coding” has varied in theoretical acceptability over the history of the study of animal learning and cognition. Pavlov (1927) recognized the complexity and interconnectedness of the nervous system and his understanding of classical conditioning emphasized the role of associative connections made between brain centers responsible for detecting stimuli and eliciting responses. Skinner (1934, 1950), by contrast, famously questioned whether theories of learning are even necessary. Hebb (1949) proposed that learning occurred by strengthening and weakening of large numbers of synaptic connections in patterns that coded experiences, which was followed by the discovery of long-term potentiation – strengthening of synapses – as the neurobiological basis of learning (Lomo 2003). This idea led to modern distributed memory models of animal learning, memory, and cognition as well as developments that led to modern learning and memory neural network modelling and artificial intelligence (AI). These approaches describe and explain coding at a synaptic level in Pavlovian and instrumental conditioning. Comparative cognition described complex learning, memory, and behavior in nonhuman animals via more complex forms of coding by specialized cognitive processes for coding of timing, counting, sequential learning, and spatial memory, among others (Hulse 1978; Meck et al. 1984; Olton 1978; Sands and Wright 1980b; Church 1980; Kesner and Novak 1982; Wasserman and Zentall 2012).

## Coding in Short-Term and Long-Term Memory

Short-term memory refers to an active, temporary, and limited storage for mnemonic codes representing recent events. Miller’s (1956) “magical number seven, plus or minus two” refers to

the approximate number of items of information that can be held in short-term memory storage concurrently in humans, which typically lasts for a few seconds or until rehearsal ends. Long-term memory has a much greater capacity and allows for codes to be stored indefinitely.

### **Coding in Retrospective and Prospective Memory**

Retrospective memory can be described as “looking back” memory, for example, remembering the cue that recently occurred. In contrast, prospective memory involves “looking ahead” memory, such as “remembering” what response should be produced when required (Kesner and Despain 1988; Roitblat 1980; Zentall 2010). That is, retrospective memory strategies rely on remembering what was experienced in the past as cues for what will happen in the future. This type of coding contributes most of an animal’s long-term codes as it is the memory of past stimuli. Prospective coding predicts future events based on past experiences with the same or similar cues that signaled a subsequent event. Honig and Thompson (1982) showed that rats in a radial maze employed the use of these two strategies when navigating the baited arms: remembering where they have already been (retrospective) and remembering where they still need to go (prospective). Such a flexible dual-coding system provides animals with the ability to shift from retrospective to prospective memory strategies as needed.

### **Coding in Memory for Space, Time, and Number**

Spatial coding refers to learning about the location of objects in space. Research with the radial arm maze and water maze in rats demonstrated that rats’ impressive spatial navigation and memory abilities depend on the capacity to use multiple surrounding “extra-maze” cues to code spatial locations (Olton and Samuelson 1976; Morris 1982) in addition to using local cues that can guide responses directly. Other studies

demonstrated that navigating an efficient path consisting of multiple locations depends on coding via separate reference and working memory systems (Diez-Chamizo et al. 1985).

Temporal coding refers to learning about the duration or relative timing of events, which in turn depends on sensing and encoding the temporal intervals between stimuli or responses. Two prominent theories to account for animal timing behavior include scalar timing theory (Meck et al. 1985; Church 1980; Meck and Church 1982; Gibbon et al. 1984), the behavioral theory of timing (Killeen and Fetterman 1988), and concurrent interval and circadian representations of time in rats (Pizzo and Crystal 2002). Evidence for counting in animals has come from studies that sought to rule out simpler mechanisms, such as discrimination learning, as explanations (e.g., Capaldi and Miller 1988; Davis and Memmott 1982). More recently attention has turned to distinguishing the role of numerosity and numerosness in animal counting.

### **Coding in Sequential Learning and Serial Pattern Learning**

Sequential learning refers to learning to anticipate a series of events or perform a series of responses. Poorly organized sequences, such as a list of unrelated letters or digits, are difficult to encode and remember. Highly organized sequences, such as the notes of a song, are typically much easier to learn and remember.

The serial position effect is a well-known phenomenon in human and animal memory. When a list of unrelated items is presented followed immediately by a test, items at the beginning and end of the list are remembered better than items in the middle of the list (Ebbinghaus 1885/1913). With longer delays between list presentation and the test, items at the beginning of the list are still remembered better than items in the middle of the list (i.e., “primacy” is still observed), but items at the end of the list are not remembered due to the delay (i.e., “recency” is not observed). Traditionally, better performance at the beginning of the list has been attributed to coding list items in long-term memory via rehearsal whereas better

performance at the end of the list has been attributed to temporary storage of items in short-term memory so that these items are still available at the time of test. Similar results have been obtained with monkeys remembering a list of images (Sands and Wright 1980a) and rats remembering lists of eight spatial locations presented in an radial maze (Kesner and Novak 1982). In the latter study, dorsal hippocampal lesions caused impaired primacy (i.e., long-term memory was impaired) but had no effect on recency (i.e., short-term memory was spared). Thus, primacy and recency appear to rely on independent coding processes and brain systems.

Serial pattern learning is a form of learning to anticipate or perform highly structured sequential patterns. Serial pattern learning recruits multiple concurrent cognitive processes to develop a cognitive representation of the sequence of events encountered in the task (Fountain et al. 2002; Muller and Fountain 2010, 2016). In the Serial Multiple-Choice (SMC) task, rats learn a sequence of responses in a circular array. The array can be eight levers or nosepoke receptacles, one each on the walls of an octagonal chamber with hypothalamic brain-stimulation or water reward for rats (Fountain and Rowan 1995a, b; Pickens et al. 2013) or a circular array of eight discs presented on a touchscreen for pigeons with grain reward (Garlick et al. 2017). One commonly studied pattern is 123–234–345–456–567–678–781–818–repeat. This pattern consists of three element types. The first element of each chunk is termed the chunk-boundary element. Rats use phrasing cues, located as indicated by dashes in the pattern above, as discriminative cues for chunk-boundary elements (Stempowski et al. 1999; Wallace et al. 2008; Muller and Fountain 2010; Fountain et al. 2013; Kunder and Fountain 2014). Rats use counting/timing processes to anticipate chunk-boundary elements (Muller and Fountain 2010; Muller and Fountain 2016). Chunk-boundary elements are followed in the pattern by within-chunk elements. These are encoded by abstract rule learning (Fountain and Rowan 1995a, b; Fountain et al. 2007; Muller and Fountain 2010; Kunder and Fountain 2011). The pattern may also contain a violation element, that is, an element that is inconsistent with pattern

structure. In this case, the terminal element of the last “818” chunk violates the rule structure of the rest of the pattern. The violation element is typically the most difficult element to learn because no single pattern item or rule predicts the location of the violation element in the pattern. To master the violation element, rats use “multiple-item memory” (cf. Capaldi et al. 1982) consisting of up to seven pattern elements leading up to the violation element as well as other spatial or temporal cues (Kunder and Fountain 2010; Muller and Fountain 2010, 2016). Thus, rats use multiple cognitive processes concurrently to learn such patterns as shown by previous work indicating that the different element types described above are also differentially sensitive to the effects of adolescent drug exposure (Pickens et al. 2013; Rowan et al. 2015), to acute N-methyl-D-aspartate blockade (Fountain and Rowan 2000), and to muscarinic cholinergic blockade (Fountain et al. 2013; Chenoweth and Fountain 2015, 2016). Other studies with infants have shown that sensitivity to recursive hierarchical serial pattern rules emerges in infancy. Infants 8–10 months old showed evidence of sensitivity to hierarchical rule structures whereas infants 4–6 months old did not (Lewkowicz et al. 2018).

## Coding in Animal Episodic Memory

Episodic memory refers to memory for specific events that were “unique, personal past experiences” (Babb and Crystal 2006; Zhou and Crystal 2011; Crystal 2018). Developing animal models of episodic memory required successfully developing techniques for assessing “what-where-when memory, source memory, item-in-context memory, and unexpected questions” (Crystal 2018) in nonhuman animals.

## Conclusion

It can be argued that characterizing the mechanisms of coding is the *raison d’être* for the field of *comparative cognition*. Understanding coding is one of the defining problems in comparative cognition research.

Institute of Technology Bombay, Powai, Mumbai,  
Maharashtra, India

### Definition

A codon is a sequence of three nucleotides that forms the basic unit of the genetic code.

### Gene Sequences are Composed of Codons

Each protein is made of a specific sequence of amino acids that is specified by the corresponding protein coding gene. The sequence information of protein is stored at the level of DNA (Deoxyribonucleic acid). DNA is composed of a sequence of nucleotides which stores information about the amino acid sequence of the resultant proteins. DNA is first converted to RNA (Ribonucleic acid) that in turn is used to guide the synthesis of corresponding proteins.

Question arises – How is the DNA sequence deciphered into the amino acid sequence of proteins?

The answer is that nucleic acid sequences can be read as “codons.”

### What Is a Codon?

Codons are three-letter “words” that direct the protein synthetic machinery to either add a particular amino acid to the growing polypeptide chain or to initiate or terminate the synthesis of a protein. Each nucleotide acts as a letter and three consecutive nucleotides form a codon. Each codon specifies either an amino acid or acts as a start or stop signal.

Codons are usually considered in terms of RNA as RNA is the actual moiety that interacts

with the protein synthetic machinery to direct protein synthesis. The corresponding DNA sequences form the DNA codons, which is essentially the same with the exception of U (uridine) being replaced by T (thymidine).

### Advantages of a Three-Letter Codon Configuration

Codons, the underlying basis of the genetic code, are formed by three consecutive nucleotides. Triplet nature genetic code provides optimal balance in terms of requirement and complexity.

Nucleotide sequence has four possible letters: adenine (A), guanine (G), cytosine (C), and uridine (U)/thymine (T).

A single-letter word could specify only four amino acids while a two-letter word would be able to specify a maximum of  $4 \times 4 = 16$  amino acids. But there are 20 standard amino acids. So, the requirement could not be met with a two-letter code.

A three-letter code can specify up to  $4 \times 4 \times 4 = 64$  amino acids. This is enough to specify all amino acids as well as start and stop signals. Hence, triplet code satisfies the requirement. Obviously the same can be achieved by using four- or five-letter codes but the system would always prefer to avoid unnecessary complexity. This is possibly the reason why triplet code was chosen by nature.

### Experimental Identification of Codons

Experimental identification of the specificity of each triplet involved use of synthetically produced known nucleotide sequences and monitoring the incorporation of amino acids against them in cell-free systems. Initially, Nirenberg and Matthaei used homopolymers to find out the amino acid specificity of AAA, CCC, GGG, and UUU. UUU, coding for phenylalanine, was the first codon to be deciphered. Later on, Nirenberg and Leder used ribosome binding assay to decipher the rest of the genetic code. Har Gobind

Khorana used synthetic RNA with repeating units to unravel the genetic code. For example, he showed that UCUCUCUCUC, which contains codons UCU and CUC, causes incorporation of serine and leucine. RNAs with four repeating units including UAG, UAA, or UGA produced only dipeptides and tripeptides thus revealing that UAG, UAA, and UGA are stop codons.

The Nobel Prize in Physiology or Medicine 1968 was awarded jointly to Robert W. Holley, Har Gobind Khorana, and Marshall W. Nirenberg “for their interpretation of the genetic code and its function in protein synthesis.”

## The Triplet Code

The triplet code has 64 unique codons. The specificities of the codons are given in the Table 1 below:

**Start codon:** AUG codes for methionine and acts as the start or initiator codon. This is the point at which translation starts and the first amino acid is incorporated into the polypeptide chain. Usually, the first AUG after the Shine-Dalgarno (SD) sequence (prokaryotic RNA’s ribosome binding site) AGGAGG acts as the start codon, and is generally located around eight bases downstream of the SD sequence. In eukaryotes, the initiator codon is usually found inside a conserved sequence of nucleotides called Kozak consensus sequence ((GCC)RCCAUGG; R is a purine). Rarely, GUG and UUG are also used as an initiator codon. While acting as an initiator codon, they cause incorporation of methionine, although their inherent specificities are different. In prokaryotes, *E. coli* is found to use AUG 83%, GUG 14%, and UUG 3% as START codons.

**Stop codon:** Stop or terminator codons specify the site at which the translation has to end. This is where the synthesis of polypeptide chain comes to a halt and it is released from the ribosome after addition of a water molecule to the end of the chain. UAG (amber), UAA (ochre), UGA (opal) are the three stop codons. Stop codons signal the termination of this

process by binding release factors, which cause the ribosomal subunits to disassociate, releasing the completed polypeptide.

As 3 out of 64 codons are stop codons, a ribosome is expected to meet a stop codon on average after every 20 codons. Hence, the presence of multiple stop codons may be an adaptation to ensure that a polypeptide does not keep elongating if a stop codon is mutated or missed.

**Amino acid codons:** 61 out of 64 codons code for different amino acids. The specificities are listed in Table 1 below. Methionine and tryptophan are coded by single codons while leucine, serine, and arginine are coded by as many as six different codons each.

## Properties of Triplet Code

1. Code is in form of triplet codons.
2. Code is nonoverlapping, i.e., the codons are read sequentially.
3. Code is nonambiguous, i.e., a particular codon always specifies the same thing. There are minor exceptions to this.
4. Code is degenerate, i.e., multiple codons may specify the same amino acid.
5. Code is commaless, i.e., one codon starts just after the earlier one. There are no nucleotides reserved to serve as punctuation marks.
6. Code is directional. Codons are always read in 5' to 3' direction. For example, GUC is valine while the reverse CUG codes for leucine.
7. Code is universal, i.e., same genetic code is followed for all organisms, barring a few minor exceptions.
8. Some codons act to initiate translation – the start codons.
9. Some codons are reserved to terminate translation – the stop codons.

## Exceptions to the Code and Implications

There are a few rare exceptions to the otherwise universal genetic code. Use of alternate start codons GUG and UUG has already been discussed.

**Codon, Table 1** Codons and the amino acids they encode

| 1st base | 2nd base |                    |     |           |     |                       |     |                      | 3rd base |
|----------|----------|--------------------|-----|-----------|-----|-----------------------|-----|----------------------|----------|
|          | U        |                    | C   |           | A   |                       | G   |                      |          |
| <b>U</b> | UUU      | (Phe/F)            | UCU | (Ser/S)   | UAU | (Tyr/Y)               | UGU | (Cys/C)              | <b>U</b> |

## Mitochondrial Genes

Mitochondrial genetic code shows subtle variations from the universal code. Table 2 lists some of the important deviations from the standard universal code.

## Nuclear Genes

In some ciliates, the universal termination codons UAA and UAG code for glutamine. In euplotids, UGA codes for cysteine. CAG may be used in *Candida albicans* as an initiator codon. In some yeasts, CUG codes for serine rather than leucine.

## Nonstandard Amino Acids

Selenocysteine, a selenium containing analogue of cysteine, is coded by the stop codon UGA. Selenoprotein mRNAs possess a characteristic secondary RNA motif called the SECIS element (SECIS: selenocysteine insertion sequence), which allows the nearby UGA codons to be recognized as coding for selenocysteine.

Pyrrolysine is encoded by the stop codon UAG. It is found in some methanogenicarchaea and bacteria. Pyrrolysine is made up of 4-methylpyrroline-5-carboxylate in amide linkage with the <sup>ε</sup>N of lysine. A special transfer RNA encoded by pylT gene and a special class II aminoacyl-tRNA synthetase that charges the pylT-derived tRNA with pyrrolysine is needed for UAG to be recognized as coding for pyrrolysine.

## Codon Bias and Implications

Codon usage bias refers to the preferential use of a certain codon to code for a particular amino acid over synonymous codons. For example, GCC and GCG both code for alanine and are thus synonymous codons. Interestingly, in the human genome, alanine is encoded by GCC four times as often as by GCG. This is an example of codon usage bias.

It is possible that the composition of the tRNA pool drives the codon bias. Those codons are selected for which corresponding tRNAs are more abundant. This may especially be true for

**Codon, Table 2** Variations from the standard genetic code as seen in different mitochondrial genomes. N refers to any nucleotide

| Codon | Standard code | Vertebrate mitochondrial | Yeast mitochondrial | Invertebrate mitochondrial |
|-------|---------------|--------------------------|---------------------|----------------------------|
| AGA   | Arg           | Ter                      | Arg                 | Ser                        |
| AGG   | Arg           | Ter                      | Arg                 | Ser                        |
| AUA   | Ile           | Met                      | Met                 | Met                        |
| UGA   | Ter           | Trp                      | Trp                 | Trp                        |
| CUN   | Leu           | Leu                      | Thr                 | Leu                        |

fast growing organisms. For slow growing organisms, codon preferences are determined by the characteristic mutational biases of that particular genome. The contributing factors of codon bias are still unclear and fiercely debated.

Codon usage bias affects the synthesis of transgenic proteins in protein synthesizing host. The host may have different codon preferences compared to the organism from which the protein coding sequence is derived. Hence, a researcher needs to take into account the codon usage bias of the host organism and accordingly change the protein coding sequence to use the host-preferred codons.

**How Codons Actually Work: Meet the Anticodon**

Codons are recognized by complimentary binding with their tRNA counterpart, the anticodon. Anticodons, just like codons, are sequence of three nucleotides located in the anticodon arm of a tRNA. Each tRNA is specific for a particular amino acid and its codon(s). tRNAs form the bridge between genetic code and protein sequence by physically bringing a particular amino acid to lodge at its correct site in the protein sequence. Anticodon forms the codon recognition arm of the tRNA by virtue of its ability to base pair to its corresponding codon. Each tRNA has an anticodon that can bind to one or more codons of that particular amino acid.

For example, methionine is encoded by AUG (5'–3') and its corresponding anticodon is the sequence UAC (3'–5'). The following table shows the base pairing specificities of nucleotides in a codon-anticodon interaction.

| 1st (i.e., 5' end) and 2nd place mRNA codon | 1st (i.e., 3' end) and 2nd place tRNA anticodon |
|---------------------------------------------|-------------------------------------------------|
| A                                           | U                                               |
| U                                           | A                                               |
| C                                           | G                                               |
| G                                           | C                                               |
| 3rd place (i.e., 3' end) mRNA codon         | 3rd place (i.e., 5' end) tRNA anticodon         |
| A or G                                      | U                                               |
| U                                           | A                                               |
| U or C                                      | G                                               |
| G                                           | C                                               |
| U, C or A                                   | I                                               |

The base pairing rules are strict for the 1st and 2nd positions. These are the standard Watson-Crick base pairs. But in the third position, the base pairing stringency is relaxed and non-Watson-Crick base pairs are possible, allowing a single tRNA to recognize multiple codons of the same amino acid. This is known as the Wobble hypothesis. The third base pair is often called the wobble base pair.

As a result of wobble base pairing, tRNAs with anticodons like CCI (3'–5') can recognize multiple codons GGU (5'–3'), GGC (5'–3'), GGA (5'–3'), all being codons of glycine, the amino acid this tRNA is specific for.

This allows lesser number of tRNAs to carry out the translation process. A minimum of 31 tRNAs are required to translate, unambiguously, all 61 sense codons of the standard genetic code.

Anticodons, tRNAs, and ribosomes together make a well-synchronized, specific, and efficient pipeline to render the genetic information hidden in the codons into the functional form of proteins.

## Coefficient of Relatedness

Anja Widdig  
Institute of Biology, Faculty of Life Science,  
University of Leipzig, Leipzig, Germany  
Max-Planck Institute for Evolutionary  
Anthropology, Leipzig, Germany

## Synonyms

[Degree of relatedness](#); [Kinship](#); [Pedigree relatedness](#)

## Definition

The coefficient of relatedness ( $r$ ) is defined as the probability that a gene in one individual is identical-by-descent (IBD) to a gene in another individual. In other words, it is the probability that

two individuals inherited a certain proportion of genes from a common ancestor. The term was introduced by Sewall Wright (1922) and is calculated as  $r = \sum (0.5)^L$ . The calculation considers that at each generation link there is meiosis, i.e., a 0.5 probability that a copy of a particular gene will be passed on to an offspring. For  $L$  numbers of generation links between two individuals the probability is  $(0.5)^L$ . Finally, the coefficient of relatedness between two individuals is the sum of coefficients calculated for each pathway by which they share a common ancestor.

To provide an example (see Fig. 1): For full-siblings (sharing both parents) we consider  $r = 2 (0.5)^2$ , as we have two generation links from one sibling to the other (one from sibling to parent, the second from that parent to the other sibling) as well as two common ancestors (mother and father), hence two pathways to sum up the degree of relatedness.

## Kin Class Versus Degree of Relatedness

The degree of relatedness can be identical for pairs of individuals who belong to different kin classes. For example, parent-offspring dyads share, on average, 50% of their genes, but so do full-siblings (Table 1).

One class which remains difficult to establish, especially in wild populations, is the class of unrelated individuals ( $r \sim 0$ ). Today, pedigree studies of free-ranging animals may include several generations of complete pedigrees (e.g., Widdig et al. 2017), hence a complete pedigree of four generations can exclude pedigree relatedness up to this generation level. Although this creates only a minor imprecision (van Horn et al. 2008), it might be relevant to have a precise measure of relatedness even among distant relatives, depending upon the study question.

## Predicted Versus Actual Degree of Relatedness

The degree of relatedness is a theoretical expectation and hence provides mean values of expected

**Coefficient of Relatedness, Fig. 1** A simple family tree including parent-offspring dyads. In blue are the individuals for which we like to determine the degree of relatedness, in white are their two direct ancestors. The degree of relatedness of the respective dyad in blue is  $r = 0.5$ , they are full-siblings

**Coefficient of Relatedness, Table 1** Degree of relatedness in relation to kin classes. Note, it is always important to consider whether ancestors are shared by one or both kin lines

| Kin class                                     | Calculation     | Degree of relatedness |
|-----------------------------------------------|-----------------|-----------------------|
| Parent-offspring                              | $r = 1 (0.5)^1$ | 0.5                   |
| Full-siblings (both parents shared)           | $r = 2 (0.5)^2$ | 0.5                   |
| Half-siblings (one parent shared)             | $r = 1 (0.5)^2$ | 0.25                  |
| Grandparent and grandchild                    | $r = 1 (0.5)^2$ | 0.25                  |
| Aunt/uncle-niece/nephew (both parents shared) | $r = 2 (0.5)^3$ | 0.25                  |
| Aunt/uncle-niece/nephew (one parents shared)  | $r = 1 (0.5)^3$ | 0.125                 |
| Cousins (if parents are full-sibs)            | $r = 2 (0.5)^4$ | 0.125                 |
| Cousins (if parents are half-sibs)            | $r = 1 (0.5)^4$ | 0.0625                |

genetic relatedness. For full-siblings, we expect that they share 50% of their genes on average; however, the actual genetic relatedness varies around its expectation due to the random nature of recombination during meiosis (Speed and Balding 2015). Genome-wide data on humans have shown differences in realized IBD among dyads with the same predicted relatedness based on pedigrees: For human full-siblings, the mean proportion of the genome-shared IBD was 49%, as expected, but the actual degree of IBD ranged from 37% to 62% (Visscher et al. 2006). Hence, it is not surprising that the coefficient of relatedness estimated from pedigrees and the actual relatedness from genetic data often differ in empirical

studies, although they are generally strongly correlated (Städele and Vigilant 2016).

### Measuring the Degree of Relatedness

Traditionally, the degree of relatedness was established via pedigrees (Pemberton 2008). However, in natural populations, pedigrees tend to be incomplete and founder individuals (often unknown) are assumed (but usually cannot be proven) to be unrelated, which is critical when assessing the degree of inbreeding (or consanguinity) (Keller and Waller 2002). In a wide range of taxa, the degree of relatedness has alternatively been estimated from genetic markers mainly through short tandem repeats (STR or microsatellites). Studies comparing relatedness derived from genetic markers and pedigrees reported a risk of misclassifying pairs of related individuals as unrelated and vice versa in the absence of pedigree data (van Horn et al. 2008). One problem arises due to overlapping distributions of relatedness among different kin classes (Blouin et al. 1996). Recent studies stressed the power increase by applying a more complex approach such as the combination of parentage analysis, sibship reconstruction, demographic information, and likelihood analysis to classify kinship (Städele and Vigilant 2016). Future studies using Single Nucleotide Polymorphism (SNP) or whole-genome sequencing data will open several new avenues, including the possibility to correctly classify distantly related individuals.

### Application of the Degree of Relatedness

Knowledge on the degree of relatedness between individuals plays an essential role in a wide range of research areas including behavioral ecology, evolutionary biology, quantitative genetics, and conservation. For example, calculating the degree of relatedness between two individuals has been widely applied in studies on social species. In particular, it has been used to explain the evolution of social behavior via kin selection from insects to humans. Kin selection theory predicts that altruistic behavior is favored by selection if the costs of the initiator are lower than the benefits of the recipient considering the degree of relatedness between the two

(Hamilton 1964). Hence, altruistic behavior is predicted to be limited to kin, with costly altruism restricted to close kin.

## Coevolution

Vishwa Gandhi

Radiation and Photo Chemistry Division,  
Bhabha Atomic Research Centre, Mumbai, India

## Definitions

- Evolution** Evolution is a continuous process of alternation in characteristics which are inherited in biological population over generations.
- Coevolution** In biology, some naturally occurring phenomena in which two or more species evolve by reciprocally affecting each other are called coevolution.

## History

The term coevolution was coined by Paul R. Ehrlich and Peter H. Reven in 1964. But these types of evolutionary interactions have been studied many years ago in 1959. Darwin has mentioned the interaction between flowering plant and insects in his book *On the Origin of Species*.

One of the reasons for coevolution is reciprocal selective pressure on two or more species which might culminate into evolutionary arms race between the interacting species. Ultimately, coevolution results in adaptation and counter-adaptation in reproduction and survival of species interacting with each other.

## Proposed Theories

### • Red-Queen Hypothesis

According to this theory, organisms have to adapt and evolve constantly with changing environment as well as proliferate constantly to obtain reproductive advantages and to survive against continuously evolving opposing other organisms. It is also known as *Red Queen's*, *Red Queen's race*, or *the Red Queen*

effect. The Red Queen effect may result when competing species find themselves in danger, e.g., higher frequency of sexual individuals in mixed population (asexual and sexual) of fresh water snail (*Potamopyrgus antipodarum*) in the presence of trematode parasites (Jokela et al. 2003).

- **Geographic Mosaic Theory of Coevolution**

According to this theory, geographic location and community ecology play important role in coevolution of strongly interacting species in multiple populations. *Natural selection in the form of geographic mosaic, hot spot (area of strong reciprocal selection between interacting species) surrounded by cold spot (area where there is very low or no reciprocal selection), and trait remixing by means of genetic drift and gene flow* are three major parameters of geographic system that drives the coevolution in population (Gomulkiewicz et al. 2002).

Geographic mosaic may lead to either mutualism (e.g., plant and pollinator) or arms race between two species such as predator-prey, host-parasites, etc. One of the examples for coevolutionary arms race is predator whelk (*Sinistrofulgur* sp.) and the hard-shelled bivalve (*Mercenaria* sp.) prey. Whelk uses shell lips to break the shell of prey. In response to that prey has developed larger and harder shells. To beat this strategy of bivalve, whelk intensified the attack and increases their size (Dietl 2003).

Depending upon the interaction between species, coevolution is broadly divided into two categories:

- *Pairwise or Specific Coevolution*

As name indicates, this type of coevolution involves one to one interaction (i.e., coevolution of two species affecting each other), e.g., development of foot long tongue in moth in response to development of foot long flower in comet orchid plants.

- *Diffuse or Guild Coevolution*

Diffuse or guild type of coevolution involves more than two species, e.g.,

evolutionary adaptation by large number of insect species feeding on same group of plant in response to development of defensive (chemical/physical) mechanism by plant against insects.

Further, **pairwise/specific coevolution** can be divided into different categories according to type of relationship between species affecting each other's evolution.

### **Predation**

When organisms from one species survive by eating other, this kind of relationship is called predation. Prey is the organism which is being eaten by predator organism. Simply, predator dies if it does not get food and prey dies if it is eaten by predator. So, prey develops the defense mechanism to escape from the predator and predators develop ability to catch prey even more effectively. Both processes impose selective pressure on both prey and predator species. Some of the strategies and mechanisms of prey and predator which may lead to coevolution are tabulated below:

| Strategies by prey                   | Adaptation by predator            |
|--------------------------------------|-----------------------------------|
| Camouflage                           | Visual acuity                     |
| Prey escape speed                    | Speed of pursuit                  |
| Flocking and herding                 | Strategies to isolate individuals |
| Prey toxicity, aposematic coloration | Resistance                        |
| Hard seed coats                      | Large beaks                       |

Examples of predation type of coevolution are as follows:

#### **1. African Honey Badger (*Mellivora capensis*) and African Bees (*Apis mellifera scutellata*)**

African honey badger (*Mellivora capensis*) and African bees (*Apis mellifera scutellata*) are example of predation coevolution. African honey badger possesses thick and loose skin to protect itself from sting of African bees, and this property makes it relatively resistant to sting and requires full-out attack by hive. In response to this adaption of honey badger, African bees have developed the ability to

secrete pheromones as it dies to call other bees to continue attack.

## 2. Galapagos Tortoises and Cactus

Galapagos tortoises and cactus also coevolved due to dependency of tortoises on cactus for its hunger. On one of the island, tortoises are with long neck in response to higher off the ground branches of cactus. While short necked tortoises dwell on the island harboring cactus with short branches. So, in this case, cactus evolved to protect itself from being eaten by tortoises, and tortoises have developed long neck to get food from branches of cactus grow at higher level and so on.

## Parasitism

In parasitism, one species of organism (parasite) is dependent on another species organism (host) for activities such as reproduction, feeding, etc. As opposed to predation, in this type of relationship the beneficiary species does not kill the host species. In parasitism, host is under selection pressure to avoid parasitism and parasite is under selection pressure to evade host defense. In such selection pressure, host carrying advantageous allele shows selective advantages and is not affected by parasites as much and that genotype becomes common in that population. Further, to become prevalent in that population, parasite is also selected to get benefits of host population with resistant allele. This way, host parasite coevolution leads to changes in allele frequencies within population.

Examples of coevolution involving host and parasites interaction are discussed below:

### 1. *Plasmodium* (Malaria Parasite) and Human Host

*Plasmodium falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* are four species of *Plasmodium* which causes malaria in human. Out of these, *P. falciparum* is predominant infectious species which leads to death. As malarial parasites infect the red blood cells, infection in humans by parasites depends on polymorphism and distribution of genes associated with hemoglobin, blood group antigens,

thalassemias, red cell membrane molecules, human lymphocyte antigen (HLA) classes, cytokines, etc. Individuals with resistant genotype can escape from being infected by malarial parasites. To evade this resistant mechanism, parasites have the tendency to make change in genotype, especially in gene of virulence. This way, human genetic polymorphism and immune response influence the structure and polymorphism in *Plasmodium* population (antigenic drift). Again new population have different targets in human population which leads to selection pressure in human population and ultimately change in gene pool of particular regional population. This way, host and parasite both influence each other to develop resistance and mechanism to invade that resistance mechanism, respectively (Evans and Wellems 2002).

### 2. Cuckoos (*Cuculus canorus*) and Different Host Bird Species

Cuckoos do not make their own nest. They lay their eggs in nest of crow. Moreover, cuckoos extrude the eggs of the host from the nest and kill the young ones in the nest. In response to this strategy of cuckoo, host develops more efficiency to distinguish own eggs and invaders. To overcome the response of host, cuckoos counter-adapt to survive. The characters adapted by cuckoos are thickened eggshells, minimization of incubation period and morphological changes to extrude out the host eggs from the nest (Rothstein 1990). Similarly, cowbird is another parasite which parasitizes the different bird (host) species in a same way as cuckoo (Rothstein 1990).

## Mutualism

When two or more species evolve together by helping each other, the interaction is called mutualism, and their process of coevolution is called mutualistic coevolution. Mutualism is divided into two categories:

### 1. Service-Service Relationship

Two species that involve in service-service mutualistic relationship get benefits from each other by providing services to each other such

as protection from their respective predators, providing shelters, etc.

## 2. Service-Resource Relationship

In this type of mutualism, one of the species provides benefits to other by providing services by some way. On the other hand, service provider species get benefits in the form of resources such as food. It is a common type of mutualistic relationship.

Some of the examples explaining coevolution in species related with each other in mutualistic manner are discussed below:

### 1. *Acacia* Ant and *Acacia*

*Acacia* ants protect the tree from prey and other plants which compete with *Acacia* tree for nourishment and other resources. In turn, *Acacia* have coevolved itself to create pores to make dwelling space for *Acacia* ants, provide them with nourishment, and protect ants' larvae (Janzen 1966).

### 2. Birds and Bird Pollinating Flowers

The pollination of flowering plants by birds is called *Ornithophily*. As plants are dependent on birds for its pollination, plants develop some characters which attract birds. In turn, birds also get some benefits from flowering plants like food, shelter, etc. Hummingbirds and ornithophilous plants are one of the examples of such type of coevolution. In this case, ornithophilous plants have evolved their flowers in such a way that they attract the hummingbirds by producing nectar, synthesizing coloring pigments of flowers which are compatible with birds' vision as well as morphological changes of the flower to make comfortable room for birds' rostrum. Moreover, ornithophilous plants flourish most during the breeding period of hummingbirds. In return, hummingbirds also adapt with the flowering plants to make maximum use of adaptations by plants, e.g., change in the morphology of beak to accommodate its beak in long corolla of flowers to get high sugary nectar and this coevolution also helps the flowering plant to place its pollen on some body part of bird (Stiles 1981; Kay et al. 2005).

### 3. Sapotaceous Tree and Dodo (*Raphus cucullatus*)

Sapotaceous tree, also known as Dodo tree, and Dodo birds both are native of islands of Mauritius. Dodo bird is exclusive pollinator for dodo trees. Hence, the extinction of dodo birds made the dodo trees to be nearly extinct on islands (Temple 1977).

### 4. Entomophilous Flowers and Insects

Flowers dependent on insects for its pollination is called entomophilous flowers. Andrenid bee (*Andrena loniceræ*) and *Lonicera gracilipes* are examples of such kind of coevolution. Andrenid bees visit the plant for nectar, and while taking nectar, some of the pollens stick to different part of bee's body. In response to that, plant has increased the nectar production. On another side, bees have also changed in morphology of proboscis to get nectar from long corolla. This way, morphological change in bees and increased nectar production in *Lonicera gracilipes* indicate the one-to-one mutualistic coevolution between them (Shimizu et al. 2014).

## Competition

When individuals of same species or different species share same niche and have common resources, they compete with each other for their existence. In this type of interspecific interaction, competitive species impose selection pressure to each other and winning species survive. In this way, they affect each other's evolution at species level and it is called competitive coevolution. Intraspecific competitions like sexual selection, sexual conflicts (Parker 2006), etc. drive the coevolution. Mostly, a consequence of within species competition is slowed growth rate and does not contribute much toward coevolution, while dependability of different species on same resources like habitat, food, etc. leads to competitive coevolution between the species (Connell 1980). The consequences of interspecific competition are competitive exclusion, local extinction, niche divergence, change in composition and structure of community, etc.

Some of the examples explaining coevolution in species compete with each other are discussed below:

### 1. Darwin's Finches

Darwin's finches are considered to be group of around 15 different species of perching birds. Due to their geographical location, they are also known as Galápagos finches and belong to Passeriformes order and Thraupidae family. Galápagos Islands are group of 21 islands. Finches on these islands have developed different food specialization such as difference in beak size and shape to decrease the competition for utilization of same limited food resources. In addition to that they have also changed their habitat for the same and occupied different islands of Galápagos Islands. Recently, some researchers have figured out the role of 240 kb *ALXI* gene (encodes a transcription factor involved in the development of craniofacial structure) in the diversification of beak size and shape of finches to optimize the utilization of limited food resources (Lamichhaney et al. 2015).

### 2. *Trifolium repens* and Neighboring Grasses (*Agrostis capillaris*, *Holcus lanatus*, and *Lolium perenne*)

*Trifolium repens* is an herbaceous perennial plant of bean family. *Agrostis capillaris*, *Holcus lanatus*, and *Lolium perenne* are perennial grass family plants. Normally, *T. repens* plants share habitat with *A. capillaris*, *H. lanatus*, and *L. perenne*. Removal of these dominant grasses from the habitat of *T. repens* led to diversification of *T. repens* into different subpopulations. This observation by researchers supports the inter-specific competition coevolution of *T. repens* and surrounding grasses (Turkington 1989).

## Introduction

### What Is Cognition?

The **mind** is a complex system that creates and controls the fundamental functions integral to survival. It can vary in form and function across animals as well as among those belonging to the same species. **Cognition** is the study of the mind – what the mind does, how the mind accomplishes these functions, and which psychophysiological mechanisms are involved in these processes.

Although the philosophical underpinnings of the mind have been discussed as early as Ancient Greece, the scientific inquiry of cognition has only gained prominence in the last 70 years. The **cognitive revolution** ignited a renewed curiosity for the mind that was previously doused by the rise of behaviorism – the study of behavior measured solely by observable actions (Miller, 2003). Until the 1950s, the field of psychology was dominated by the belief that mental processes could not be methodologically quantified or observed. Instead, behaviorist psychologists, such as John B. Watson and B.F. Skinner, focused on behavioral responses to environmental stimuli. Advancements in computer technology catalyzed the rise of the cognitive revolution – particularly the discovery that machines were capable of performing logical operations. Scientists began to wonder if computers worked in the same way the human brain does. When they realized there was little research on the mind, researchers shifted their focus from behavioral psychology to cognition. The pioneers of cognition include Ulric Neisser (referred to as the “father of cognitive psychology”), Norman Chomsky (linguistics), and George Miller (memory).

Today, cognition is one of the main subfields of psychology. It is often studied alongside other

disciplines such as philosophy, neuroscience, linguistics, computer science, and anthropology. Key areas of cognition include perception, attention, memory, and language.

The study of cognition is not restricted to the human mind. Many cognitive scientists are interested in the mental processes of other species such as mammals, birds, and even sea creatures. Researchers may study nonhuman minds in order to gain a better understanding of those species' cognition. They may also study other species' brains in order to learn more about the human brain. For example, the human brain may be difficult to study because it involves many potential risks and costs to the participants. This may be especially true for drug treatments or lesions to the brain that are potentially harmful to human subjects. In contrast, mice brains, which are similar to human brains in structure and function, are easier to study and are more accessible. Therefore, it is common for cognitive scientists to study mice before or in place of human subjects.

### Methodologies

Cognitive scientists employ a range of research methods to evaluate the mind. They may use these approaches to study cognition within or between different species. Similar to other sciences, cognition can be studied and explained distinctly or across three domains: mental, behavioral, or psychophysiological. When cognition is evaluated at the mental level, it is often explained using theories and/or models such as computational, box-and-arrow, or statistical. **Cognitive theories** explain how a mental phenomenon occurs, what components are involved, and which outcomes are expected as a result of this process. These underlying cognitive mechanisms can be observed through the behavioral level. Behaviors can be measured by means of a performance on an activity such as a task or questionnaire. Finally, the psychophysiological level measures the physiological responses that arise as a result of the behavioral and cognitive levels. Examples of physiological responses include brain activation by means of an imaging machine (e.g., EEG, fMRI, or PET), electrodermal activity (e.g., skin responses), cardiovascular measures, or eye movements.

Consider the following example regarding the study of attention. There are different theories that explain how individuals process the environment and attend to particular stimuli in that environment (e.g., Broadbent's filter model of attention). Attention may be observed by means of a behavioral task in which participants have to watch a video and count the number of cars that appear on the screen. Lastly, participants can be connected to an eye-tracking device where their pupil dilations and eye movements are observed as they attend to the cars in the videos.

### Perception

How do species perceive the world? How do dogs smell? How do humans hear a friend's voice in a crowd? How do mice taste cheese? Species have sensory systems dedicated to each of the five **senses** – taste, touch, sight, vision, and smell. In these systems, sensory information is captured by means of **sensory receptors**, or specialized nerve cells designed to respond to specific sensory stimuli. These sensory stimuli are then converted into electrical impulses, which are then interpreted by the brain. This process results in a **sensation**, or a detected stimulation from the internal or external world. Different species experience the world through sensations, and their interpretations of those sensations determine their perception.

**Perception** is the process by which species identify, organize, and interpret those sensations (Levine and Shefner, 2000). For example, humans identify vibrations in the air, organize them into sound waves, and interpret them as music. Perceptual processing is complex – involving the interplay of body organs, neural networks, and environmental information. Although it is difficult to confirm how nonhumans perceive the world, scientists believe that they have similar sensory receptors and brain activation as humans. Differences in these physiological systems could result in changes in perception. In order to understand the complexity of perception, consider how species see the world. Seeing requires visual sensation and visual perception.

**Visual sensation** is the process by which electromagnetic rays – in the form of visible light – are processed from the eyes to the brain (Levine and Shefner, 2000). When a living or nonliving thing occupies space, light bounces off that object and into the visual sensory organ, or the **eyes**. The **cornea** and **lens** focus the light while the **pupil** – with the help of the **iris**, which opens and closes – regulates the amount of light that passes through the eyes. The cornea, pupil, iris, and lens work together to direct the light towards the back of the eye to the retina. The **retina** contains photoreceptors with specialized sensitivities that work together to provide vision. **Photoreceptors** respond to light in the environment and convert them into electric signals, which are later processed and decoded in the brain.

There are two types of photoreceptors: rods and cones. Although the **rods** and the **cones** both respond to light, they respond to it in different ways. **Rods** are responsible for vision in low-light environments. They detect movement, shape, as well as light and dark changes. **Cones** are responsible for color vision. Rods and cones also differ in sensitivity and acuity. Rods are extremely sensitive to light – meaning they are able to detect and respond to as little as a photon of light. However, rods have low acuity, which means they cannot detect fine details in the environment. In contrast, cones are less sensitive but have greater acuity. Cones require more light for detection. This increase in bright light allows cones to detect small details in the environment.

The photoreceptors transform visible light into electric signals. Then, these neural impulses travel through the optic nerve, optic chiasm, and optic tract – ultimately leading towards the visual cortex for processing. **Visual perception** is the process by which these electric signals are identified, organized, and interpreted in the brain to create the visual world. There are two visual streams: The What and Where Pathways (Ungerleider and Mishkin, 1982). The ventral stream (**What Pathway**) is involved in **object recognition**, or the ability to discriminate between objects. On the other hand, the dorsal stream (**Where Pathway**) is involved in **spatial recognition**, or the ability to determine how an

object occupies space. Visual perception could be divided into four categories: color, object, depth, and motion perception.

**Color perception** involves three stages: (Goldstein, 2011). In **detection**, cones respond to light wavelengths in the environment. In **discrimination**, these wavelengths are differentiated as different perceived colors. In the electromagnetic spectrum, distinct wavelengths lead to the perception of particular colors. For example, long wavelengths are perceived as the color red while short wavelengths are observed as blue. Medium wavelengths are perceived as green. Finally, **appearance** is the process by which these perceived colors are assigned color names.

Do animals see color like humans? Although it is difficult to confirm what animals actually see, scientists have made inferences based on the number of cones in their eyes. For example, dogs and mice have fairly few cones in their eyes. Scientists believe they primarily see the world in greys, blues, and yellows. In contrast, monkeys and birds are believed to have relatively good color perception.

**Object perception** is the process by which species recognize objects in the environment. Early scientists believed that each neuron coded specific stimuli in the environment. Through **specificity coding**, they believed that species had a neuron for each object in the environment (e.g., banana neuron or grandmother neuron) (Gross, 2002). However, scientists now believe that object perception is achieved through **distributed coding** in which objects are processed through a network of neurons. Species' ability to perceive objects depends greatly on where their eyes are placed. For example, many predators (e.g., primates) have eyes in the front of their heads, which allow them to detect prey. On the other hand, many prey (e.g., bunnies) have eyes on the sides of their heads, which allow them to see predators in order to avoid being eaten.

**Depth perception** is the ability to perceive the world in three dimensions. Species can detect depth based on **depth cues** – or information determining distance between and among objects – in the environment. **Monocular depth cues** are depth information that is available even when

the world is perceived with one eye alone, or **monocular vision**. They include:

1. **Occlusion**: understanding that closer objects obstruct view of other objects
2. **Relative size**: comparison of size between two objects without knowing absolute size of either one
3. **Texture gradient**: understanding that closer objects will have more visible fine details compared to objects further away
4. **Relative height**: understanding that objects at different distances from the viewer will form different heights on the ground plane
5. **Familiar size**: depth information based on knowledge of typical size of objects
6. **Aerial perspective (atmospheric perspective)**: depth understanding that objects that are farther away appear blurrier, bluer, and more scattered
7. **Linear perspective**: understanding that parallel lines in the 3D world will look like they converge in 2D images
8. **Vanishing point**: the apparent point where parallel lines recede in depth convergence

**Binocular depth cues** are depth information that is available when the world is perceived with two eyes, or **stereoscopic vision**. With two eyes, species can perceive the same object at two slightly different angles. This information is then combined in the brain to form depth information about three-dimensional images in the environment.

Finally, **motion perception** is the ability to perceive movement in the environment. Evolutionarily, some species developed motion perception in order to identify dangers in their surroundings. Motion perception is possible through **delay circuits**, which detect and combine information regarding the same object. As an object appears to move in the receptive field, that object is perceived to be moving. **Akinetopsia** is the inability to perceive motion.

Like with vision, perception of other sensory information is complex and specialized. These different processes include sound perception, taste perception, touch perception, and odor perception.

## Attention

The world is overwhelmingly full of response-seeking sensory information. Consider a monkey inhabiting a forest. In any given moment, its environment may consist of different sounds (e.g., its mate's voice calling it towards them or the bustle of other animals in the distance), sight (e.g., the appearance of its predator coming towards it or the sight of fruit on a nearby tree), and touch (e.g., the feel of the tree branches on its hands or the dirt on its feet from walking on the ground). Researchers believe that most species are unable to perceive and respond to all of the sensory information in its environment. Instead, most species can only attend to a limited capacity of environmental information. **Attention** is the ability to focus on a particular stimulus at any given time. The two main regions in the brain associated with attention are the prefrontal cortex and the parietal cortex.

Therefore, among these competing sensory information, how do species navigate their environment in order to survive? For example, if the monkey is too focused on the other stimuli, it may not see the hungry eagle approaching. It may also perceive the other sensory information in a way that leads them to overlook the fruit on the tree or their mate for reproduction. **Selective attention** is the ability to direct attention towards task-relevant information while disregarding other irrelevant information (James, 1890). In other words, if the monkey is hungry, then it is able to attend to the fruit on the nearby tree. If the monkey wants to reproduce, it may be especially focused on listening to its mate. Attention helps species filter relevant information from their environment in order to perform adaptive behaviors.

In order to selectively attend to their visual surroundings, species need to shift their focus from one stimuli to another – thereby shifting their fixations. **Fixation** is the maintenance of visual gaze on a particular location. **Overt attention** is the ability to shift attention using eye movements (Goldstein, 2011). There are four types of eye movements: saccades, smooth pursuit movements, vergence movements, and vestibulo-ocular movements. **Saccade eye**

**movements** are rapid, ballistic movements of the eyes between fixation points. Saccades cannot be controlled. Contrastingly, **smooth pursuit movements** are much slower and involve steady movement. Smooth pursuit movements are controlled. **Vergence eye movements** focus the fovea of both eyes on nearby stimuli. Lastly, **vestibulo-ocular movements** help compensate for head movements and help stabilize the eyes in order to attend to environmental stimuli. Most animals rely on overt attention to attend to particular stimuli in their environment.

Additionally, species can focus on environmental stimuli through **covert attention**, or the ability to shift attention without eye movements (Goldstein, 2011). Researchers have created different attention models for humans, with varying degrees of **selection** – the process of focusing on relevant information from the environment – from early (Broadbent, 1958), intermediate (Treisman, 1964), to late (Deutsch and Deutsch, 1963). Regardless of these distinctions in selection, covert attention models involve perceiving the environment, filtering out irrelevant information, and isolating goal-appropriate stimuli. These covert attention models are based on human functioning, but they have been speculated to apply to other species (e.g., rats and monkeys).

**Attention span** determines how long a species can focus on a particular stimulus at once. Some species have relatively short attention spans (e.g., fruit flies with 3 seconds) while others can attend to stimuli longer (e.g., sparrows). On average, humans can focus on a particular stimulus for 8 seconds and can sustain attention on tasks from 5 to 20 minutes.

Sometimes, species need to attend to multiple stimuli in the environment in order to perform a task. For example, driving requires attention to the road ahead, to the signs and landmarks in the distance, and to other motor vehicles on both the left and right sides. **Divided attention** is the ability to focus on multiple stimuli at one time. Divided attention abilities differ depending on task difficulty and automaticity. It is easier to attend to stimuli that are relatively simple. For example, it is easier to attend to both a red circle and a blue square on a computer than it is to keep

track of three pots of food cooking simultaneously. Furthermore, it is easier to perform tasks that have frequently been performed in the past. However, humans have difficulty sustaining divided attention in order to complete multiple tasks at once, or multitask. For example, research shows that most driving accidents result from unsuccessful multitasking (e.g., driving and talking on the phone or driving and texting) (Dingus et al., 2006; Strayer and Johnston, 2001).

In addition to difficulty multitasking, humans have a tendency for **inattention blindness**, or perceptual blindness. **Inattention blindness** is categorized by a failure to attend to an unexpected stimulus in plain sight – often because one is focusing on something else in the environment (Mack and Rock, 1998). For example, in an attempt to count the number of ball passes during basketball team practice, one may fail to see a person in a gorilla suit walking across the basketball court (Simons and Chabris, 1999).

Another example of the limitations of attention is **change blindness** – or the failure to notice changes in a visual stimulus (Rensink, 2002). For example, when humans are shown a scene (e.g., a street) and are then shown a second image with minor changes (e.g., different street signs, different fire hydrant colors, different store fronts), they have difficulty identifying these modifications. Change blindness has also been observed in other animals including chimpanzees and pigeons.

## Memory

Most adaptive behaviors require information from previous stimuli or environments. Consider a bird searching its environment for food. The bird must be able to remember the type of food it eats (e.g., fruit), what they look like, where they are typically located, and how to procure them. Without this ability to remember information about its food, birds would have difficulty satisfying their hunger. **Memory** is the process by which information is encoded, stored, and retrieved. Evolutionarily, species use memory in order to navigate their environment, avoid dangers, and complete

tasks. Memory has been categorized in three forms: short-term, working, and long-term memory.

**Short-term memory** is a limited-capacity system responsible for storing small amounts of information over short periods of time, or up to 30 seconds. In short-term memory, information can be represented, or **coded**, in three different ways: auditory, visual, and semantic. **Auditory coding** is based on sounds (e.g., the sound of a partner's voice) (Conrad, 1964). **Visual coding** is based on an ocular representation (e.g., the image of a cat) (Kroll, 1970). Finally, information can be represented **semantically** (e.g., traffic report on a radio station) (Wickens et al., 1976).

How much information can be stored in short-term memory? In humans, researchers have tried to measure short-term capacity using **digit spans**, or the number of digits a person can remember for a short period of time. When presented with a string of numbers, humans can typically remember five to nine items (Miller, 1956). However, humans can maximize the amount of items in their short-term memory by **chunking**, or grouping individual units into larger ones (Miller, 1956). Consider the following digits, "123403221974." Instead of attempting to remember 12 individual digits, humans are better able to remember four groups: "1234," "03," "22," and "1974."

Unlike humans, many animals have smaller short-term memory capacities. Though they store useful information necessary for survival, they often forget everything else. For example, some studies suggest that dogs forget an event happened at all after 2 minutes. However, there are some animals with even better short-term memory than humans. For example, elephants can keep track of as many as 30 family members at once. Human short-term memory lasts as long as 30 seconds, whereas cats can last at least 10 minutes.

Similar to short-term memory, **working memory** also provides limited and temporary storage of information (Baddeley and Hitch, 1974). However, working memory manipulates that information in order to complete tasks such as reasoning and judgment (Baddeley, 2000). For this reason, working memory is considered a "mental workspace" because it also serves processing

functions. Consider the addition of two digits, 21 and 37. In working memory, not only are these two digits temporarily stored, but they are also used to complete the task at hand. Human working memory involves three components: the phonological loop, visuospatial sketchpad, and central executive.

In the **phonological loop**, the **phonological store** holds verbal and auditory information for a few seconds while the **articulatory rehearsal loop** is responsible for rehearsing this information (Baddeley et al., 1984; Baddeley, 2000). Rehearsal prevents decay, or forgetting, of that information. For example, the phonological loop is useful for remembering a person's name or phone number. The **visuospatial sketchpad** holds visual and spatial information (Shepard and Metzler, 1971). It is useful for maneuvering around an environment or solving a puzzle. Finally, the **central executive** is responsible for coordinating the phonological loop and visuospatial sketchpad as well as pulling information from long-term memory in order to accomplish the task at hand (Baddeley, 1996).

Finally, **long-term memory** is a system that stores relatively more information – compared to short-term and working memory – over long periods of time. It is difficult to determine the extent to which other animals have long-term memory. Consequentially, most long-term memory knowledge is based on human processing. The duration of time can entail a few minutes or as long as an entire lifetime. Long-term memory can be divided into two categories: explicit memories and implicit memories (Goldstein, 2011). **Explicit memory**, or declarative memories, is the storage of conscious information. It consists of semantic memory and episodic memory. **Semantic memory** is the recollection for facts and general knowledge. An example of this type of memory may include knowledge that the telephone was invented in 1876. On the other hand, **episodic memory** is the recollection of personal experiences. An example of this type of memory may include the first time one used a cellular telephone.

In addition to explicit memories, long-term memories can also consist of implicit memories.

**Implicit memory**, or non-declarative memory, is the storage of unconscious information. It is comprised of **procedural memories** – recollections for performing actions and tasks. Examples of procedural memories include chewing and biting, walking, as well as riding a bicycle or flying. Both humans and nonhumans have been shown to produce some form of procedural memories.

Information can be forgotten both in short-term memory and long-term memory. Because short-term memory storage has limited capacity, information can be lost through **displacement** – the process of pushing out current information in order to accommodate the new information. Forgetting long-term memory information can occur due to a lack of consolidation, or due to interferences or decaying. It is possible that the information was not adequately consolidated into long-term memory in the first place. For example, research shows that students who cram material for a test have more difficulty recalling that information during later tests (e.g., midterm or final) – assuming they did not try to study it again after initial testing. In addition, information in long-term memory may also be forgotten due to **interference** – when past memories interact with new memories.

Lastly, information can be forgotten in long-term memory through **decaying** – the fading of memory over time. This suggests that the more time that passes since the memory is recalled, the harder it is to recall in the future. Consider a word learned in a college Japanese class: *Hiru*. A student may easily recall the word for the quiz and even the final. He or she may even bring it up in conversation a couple years after college. However, the student may have difficulty recalling the word *Hiru* after 50 years.

## Language

**Language** is a system of communication involving meaningful symbols (e.g., sounds or gestures) (Goldstein, 2011). The ability to communicate with other members of one's own species serves a multitude of adaptive functions. For example, one may learn about potential dangers in an

environment or gain information about food and shelter. Additionally, language is useful when signaling a mate for reproduction. Language has been studied in humans as well as nonhumans.

Human language is comprised of five components: phonology, morphology, syntax, semantics, and pragmatics. **Phonology** is the study of sound. In language, **phonemes** are the smallest distinctive unit of sound. On the other hand, **morphemes** are the smallest meaningful units of language. **Morphology** refers to the study of morphemes – how they're formed and organized, as well as their relationship to one another. Morphemes can be prefixes, suffixes, roots, or individual words. Consider the following word, *car*. The three phonemes – “c,” “a,” and “r” – each produce distinct sounds. The whole word is considered one morpheme. However, consider the word, *carwash*. In this example, there are six phonemes: “c,” “a,” “r,” “w,” “a,” “sh.” Furthermore, *carwash* contains two morphemes: “car” and “wash.”

Additionally, human language involves **syntax** – a set of rules governing how words are sequenced. More specifically, syntax is the grammatical structure that dictates the order in which morphemes are combined. For example, syntax determines the arrangement of subject, verb, and object. **Semantics** refers to the meaning of the string of words. For example, *Jessica reads the book* and *The book is read by Jessica* have different syntax, but they are semantically the same. Lastly, **pragmatics** is the study of how context affects meaning. Referred to as the social language, pragmatics comprises of how species use language to interact with others. It entails what is said, how it is said, and the appropriate context in which to say it.

Humans develop language within the first years of their life (Gleason and Ratner, 1998). They can discern between sounds at 3 months old, and they begin producing sounds at 6 months old – also known as **babbling**. From ages one to three, they learn morphemes and syntax. By the time they finish grade school, children have rudimentary command of their language. Throughout their lifespan, humans continue to build on that language: longer morphemes, more complex syntax, and more advanced pragmatics.

Researchers have hypothesized the reason for language development. The three main theories of language development are the nativist theory, social interactionist theory, and learning theory. The **nativist theory** suggests that each human being is born with the capacity to acquire language. Noam Chomsky, a renowned psychologist and linguist, postulates that humans have a **language acquisition device** – an innate mechanism used for language acquisition (Chomsky, 1986).

However, some researchers do not believe language is developed innately. The **social interactionist theory** hypothesizes that language is developed as a result of social interactions. Interactionist theorists, such as Lev Vygotsky, believe children learn language by imitating and adopting words and rules used by adults (Gallaway and Richards, 1999). Consider the grammar mistakes toddlers make in their first years of language. They argue that children say “goed” instead of “went” because they are incorrectly imitating grammar rules of other words.

Finally, **learning theory** postulates that children acquire language through reinforcement. Learning theorists believe that infants are rewarded for communicating through language, which lead to repetitions of that behavior. For example, when infants communicate any variation of the word “mom” (e.g., *mah* or *mama*), they are rewarded with positive facial expressions (e.g., a smile) and gestures (e.g., a hug or kiss).

Is language unique to human beings? Remarkably, animals also engage in communication with members of its own species. **Animal language**, or animal communication, is the way in which nonhuman species use sounds and gestures to communicate with one another. However, researchers believe that animal language is different than human language. There are six properties that differentiate human language from animal communication: arbitrariness, discreteness, displacement, duality, productivity, and semanticity. Researchers have observed certain animals share some, but not all, of these language properties. However, it is difficult to confirm the capacity at which animals can and do use language. These are the following properties of human language:

1. **Arbitrariness:** In human language, there is an absence of any natural connection between the way a word sounds or formed and the word’s meaning. For example, the word *cup* does not give any indication of what a cup looks like or what it is. Overall, human language is arbitrary. Animal communication also possesses some arbitrariness. For example, chimpanzees are able to signal danger by vocalizing a sound, which has no resemblance to the meaning of danger.
2. **Discreteness:** Human language is comprised of a combination of small, distinct units. Furthermore, changes – no matter how minor – among these units create completely different meanings. For example, simply changing the “r” in the word *rose* to an “n” changes the meaning of the word from a type of flower to a body part responsible for smell. Similarly, bats are able to communicate with one another through different amalgamations of distinct sounds. Elephants have also been observed to have a variety of different distinct units of communication.
3. **Displacement:** Human language can be used to communicate about objects, place, people, events, or ideas that are not in the immediate time or space. For example, a friend can talk about their sibling who is studying abroad, a breaking news segment on the television the morning prior, or the concept of immortality and death. Animal communication can possess displacement. For example, bees engage in an intricate and special dance in order to communicate the location of food – its direction and distance from the hive.
4. **Duality:** Human language is comprised of meaningful words and sounds that can be broken down into meaningless units (e.g., morphemes into phonemes). For example, the word, *phone*, denotes significance, whereas “p,” “h,” “o,” “n,” and “e” do not have intrinsic meaning. Because human researchers have difficulty identifying which sounds constitute as language for animals, they are uncertain if animal communication also involves duality.
5. **Productivity:** Human language has the potential to produce infinite different meanings and messages by combining the elements

differently. For example, there are at least 200,000 words in the English language – alluding to the creation of a multitude of different sentences and phrases. Similar to duality, researchers do not know the number of elements involved in animal communication. Therefore, it is hard to determine whether or not animal language can produce infinite different meanings from these symbols.

6. **Semanticity:** Human language has a stable and specific relationship between signal and meaning. For example, the word *water* will always have the same connotation, regardless of whether it is said or spoken in Japanese, Spanish, or Swahili. Animals also have different signals that signify meaning. For example, certain species have distinct gestures to communicate with mates and signal reproduction. This may involve a vocalization (e.g., penguins engaging in a mating call) or performance of a behavior (e.g., peacocks showing feathers).

## Cognitive Bias

Fernando Blanco

Universidad de Deusto, Bilbao, Spain

### Definition

Cognitive bias refers to a systematic (that is, non-random and, thus, predictable) deviation from rationality in judgment or decision-making.

### Introduction

Most traditional views on human cognition propose that people tend to optimality when making choices and judgments. According to this view, which has been pervasive in many cognitive sciences (particularly Psychology and Economics), people behave like rational, close-to-optimal agents, capable of solving simple as well as complex cognitive problems, and to maximize the rewards they can obtain from their interactions with the environment. Generally, a rational agent would weight potential costs and benefits of their actions, eventually choosing the option that is overall more favorable. This involves taking into consideration all the information that is relevant for solving the problem, while leaving out any

irrelevant information that could contaminate the decision (Stanovich 1999). Whole research areas in social sciences have been built upon this assumption of rationality (see, e.g., the *Homo Economicus* theory in Economics).

However, this traditional view has been challenged in the last decades, in light of evidence coming from Experimental Psychology and related areas. Thus, a growing body of experimental knowledge suggests that people's judgments and decisions are often far from rational: they are affected by seemingly irrelevant factors or fail to take into account important information. Moreover, these departures from the rational norm are usually systematic: people fail consistently in the same type of problem, making the same mistake. That is, people seem to be irrational in a predictable way (Ariely 2008). Therefore, a theory that aims to model human judgment and decision-making must, in principle, be able to explain these instances of consistent irrationality or cognitive biases.

We can begin to examine the concept of cognitive bias by describing a similar, easier to depict, type of phenomenon: Visual illusions. Figure 1 represents a famous object configuration, the “Muller-Lyer illusion” (Howe and Purves 2005). The reader must observe the picture and decide which of the two horizontal segments, a or b, is longer.

In Western societies, most people would agree in that segment b looks slightly longer than segment a. In fact, despite this common impression, both segments a and b have exactly the same length. These segments only differ in the orientation of the adornments that round off the edges (i.e., “arrows” pointing inward or outward), which are responsible of creating the illusion that they have different lengths (Howe and Purves 2005). This example of a very simple visual illusion illustrates how people's inferences can be tricked by irrelevant information (the adornments), leading to systematic errors in perception. A similar situation can occur across a variety of domains and tasks, revealing the presence of cognitive biases not only in perception but also in judgment, decision-making, memory, etc.

**Cognitive Bias, Fig. 1** The Muller-Lyer illusion (Adapted from Howe and Purves (2005) by the author)

Typically, the consequence of cognitive bias is a form of irrational behavior that is predictable (because it is systematic). Cognitive biases have been proposed to underlie many beliefs and behaviors that are dangerous or problematic to individuals: superstitions, pseudoscience, prejudice, poor consumer choices, etc. In addition, they become specially dangerous at the group-level, since these mistakes are systematic rather than random (i.e., one individual's mistake is not cancelled out by another one's), leading to disastrous collective decisions such as those observed during the last economical crisis (Ariely 2009).

## Potential Causes

Traditionally, research on cognitive biases has tended to elaborate taxonomies, or lists of experimentally documented biases, rather than focusing on providing explicative frameworks (Hilbert 2012). Consequently, this is the way in which many textbooks and introductory manuals approach the topic: e.g., Baron (2008) lists a total of 53 biases in his introductory book to *Thinking and Deciding*.

Nonetheless, some authors attempted to offer coherent conceptual frameworks to understand what all these biases share in common and how they originate. Here, we list some of the approaches that have tried to account for cognitive biases: limited cognitive resources, influence of motivation and emotion, social influence, and heuristics. They will be examined in turn.

## Limited Cognitive Resources

First, an obvious explanation for many reported cognitive biases is the limited processing capacity of the human mind. For example, since people's

memory does not possess infinite capacity, we cannot consider any arbitrarily big amount of information when we make an inference or decision, even if all this information is relevant to the problem. Rather, we are forced to focus on a subset of the available information, which we cannot process in detail either. Therefore, in most complex problems, the optimal, truly rational solution is out of reach and we can only aim at "bounded rationality" (Kahneman 2003), that is, making the best decision after taking into consideration a limited amount of information. This explanation works well to explain certain instances of cognitive bias, such as the problems associated to thinking with probabilities. In particular, research has documented that people tend to neglect base rate information when making Bayesian inferences (i.e., a cognitive bias). However, the same problem is solved much more easily when it is formulated in terms of frequencies, rather than in probabilities (Gigerenzer and Hoffrage 1995). The calculations become simpler in the latter case just because of the more natural presentation format, and the bias seems sensitive to this manipulation.

## Emotion and Motivation

Another potential cause for at least some cognitive biases is emotion or affect. Traditionally, research on decision-making understands rationality as "formal consistency," conforming to the laws of probability and utility theory. Then, emotions are left out the rational decision-making process, as they can only contaminate the results. However, subsequent research shows that emotions play a substantial role in decision-making (Bechara and Damasio 2005) and suggests that without emotional evaluations, decisions would never reach optimality. After all, emotions are biologically relevant because they affect behavior: e.g., we fear what can harm us, and consequently decide to avoid it. Several cognitive biases could be explained by the influence of emotions. For instance, the loss-aversion bias (Kahneman and Tversky 1984) consists of the preference for avoiding losses over acquiring

gains of equivalent value, and it could be driven by the asymmetry in the affective value of the two types of outcomes. Other examples concern moral judgment. Many typical studies on moral judgment consist of presenting participants with fictitious situations such as the famous “trolley dilemmas” (Bleske-Rechek et al. 2010). In one simple variant of the problem, participants would be told that a trolley is out of control, barreling down the railways. Close ahead, there are five people tied up to the track. The participant could pull a lever to divert the trolley to a side track, in which there is one person tied up and unable to escape. Would the participant pull the lever? From a rational viewpoint, the utility calculus seems straightforward: it is preferable to save 5 people (and kill one) than the opposite outcome. Most people behave according to this utilitarian, rational rule. However, we know that the participants’ decisions in these dilemmas are sensitive to affective manipulations: for example, if the person who lies on the side track is a close relative of the participant (or their romantic partner), this would affect the decision (Bleske-Rechek et al. 2010). Therefore, emotions can drive some systematic deviations from the rational norm.

A related potential source of bias is motivation. Research has shown that people’s inferences can be biased by their prior beliefs and attitudes. That is, they can engage in motivated reasoning (Kunda 1990): when solving a task, they choose the beliefs and strategies that are more likely to arrive at conclusions that they want to arrive at. For example, participants who had to judge the effectiveness of gun-control measures to prevent crime exhibited biased processing of contingency information to eventually align with their initial attitudes toward gun control (i.e., “motivated numeracy”) (Kahan et al. 2012). This could explain many other instances of bias in reasoning and behavior.

## Social Influence

Certain cognitive biases could be produced, or at least modulated, by social cues. For instance,

Yechiam et al. (2008) examined the risk-aversion bias in a gambling task: typically, the bias consists of people preferring a sure outcome over a gamble of equivalent or higher value. Crucially, the researchers found that the bias was reduced when participants were observed by their peers. Other cognitive biases possess a more fundamental link to social cues. It is the case of the bandwagon bias, which describes the tendency of people to conform to the opinions expressed earlier by others, and which has strong influence in collective behaviors, such as voting in elections (Obermaier et al. 2015). So far, we do not know whether the contribution of social cues to this and related biases are due to people’s preference to conform to their peers or because people use others’ opinions as a source of information to form their judgments.

## Heuristics and Mental Shortcuts

Perhaps the most successful attempt to provide a coherent framework to understand cognitive biases is Kahneman and Tversky’s research program on heuristics (Kahneman et al. 1982). The rationale of this approach is as follows. First, making rational choices is not always feasible, or even desirable, for several reasons: (a) it takes time to effortfully collect and weight all the evidence to solve a problem; (b) it also needs the investment of lots of cognitive resources that could be used for other purposes; and (c) quite often a rough approximation to the best solution of a problem is “good enough,” whereas keeping on working to get the optimal solution is so expensive that it does not pay off. Therefore, the mind uses heuristics, or mental shortcuts, to arrive at a conclusion in a fast-and-frugal way. A heuristic is a simple rule that does not aim to capture the problem in all its complexity or to arrive at the optimal solution, but that produces a “good enough” solution quickly, and minimizing the effort. At this point, we can recover the example of the Muller-Lyer illusion that we described above, to realize that it can be explained as a heuristic-based inference. In real life, people’s visual system must handle three-dimensional

information to make inferences about distances and depth. This is highly demanding in terms of resources. However, the task can be simplified by looking for simple rules. Our cognitive system seems to interpret the visual input by making use of certain invariant features of the environment. In a three-dimensional world, two segments that converge at one point (as in Fig. 1) usually indicate a vertex (e.g., the edges formed by adjacent walls and ceilings typically display this configuration). The orientation of the edges can be used to predict whether the vertex is incoming (panel a) or outgoing (panel b) (first invariant). Furthermore, an edge far away from the observer will look smaller than one that is near (second invariant). In the real world that we navigate most of time, applying these two simple rules serves to correctly infer depth and distance, without implementing a costly information processing procedure. However, Fig. 1 is not a three-dimensional picture, and this is why applying the simple rules (heuristics) leads to an error or an illusion: incorrectly perceiving depth in a flat, bi-dimensional arrangement of lines and, thus, incorrectly judging the sizes of the segments. Nonetheless, Fig. 1 can be thought of as an exception, whereas most of visual configurations we see everyday actually confirm the simple rules, which explains why the heuristic is useful. In conclusion, as illustrated by the visual illusion example, judgment can be biased by the operation of heuristics that exploit regularities or invariants in the world. These heuristics are simple rules that can be expressed in an intuitive manner (such as “distant objects are seen smaller”) and need little time and effort to reach a conclusion (i.e., they are economic). While they lead to conclusions that approximate a good enough solution most of the times, they can also lead to systematic mistakes.

A great deal of experimental research has documented several heuristics that could underlie many cognitive biases. Perhaps the most famous ones are the representativeness heuristic, the availability heuristic, and the anchoring-and-adjustment heuristic (Gilovich et al. 2002).

**Representativeness** This heuristic is based on similarity or belonging and can be intuitively

formulated as “if A is similar to B (or belongs to group B), then A will work in the same way as B does.” That is, when an exemplar is perceived as representative of the group, all the features that are typical of the group are attributed to the exemplar. An example could be that of deducing that a given person is smart, just because he studies at the university or because he wears glasses. This heuristic can explain why people commit certain errors when solving Bayesian reasoning problems, such as the base-rate neglect (Bar-Hillel 1980).

**Availability** The availability heuristic is based on the ease with which a representation comes to mind. If a certain idea is easy to evoke or imagine, then it is incorrectly judged as likely to happen. A classical example is the reported overestimation of the likelihood of an airplane crash after watching a movie about airplane accidents. This heuristic can account for many common biases, such as recency bias: the piece of information that is the last in being presented is also the most easily remembered, and therefore it is usually weighted more heavily than other pieces of information, which can lead to serious errors in many domains (e.g., judicial). Another instance of the operation of the availability heuristic is the evaluation of near-win events: the fourth runner in crossing the finish line in a race often feels worse than the tenth one. This happens because this person can vividly imagine him/herself as being the third.

**Anchoring and Adjustment** This is sometimes considered as a special case of the availability heuristic. Knowing a tentative answer to a question is known to bias further attempts to answer (these answers become closer to the anchor). For instance, imagine that you are asked the question: “in which year did Albert Einstein visit the USA for the first time?”. Let us assume that you do not know the answer, so you must guess. Most people would pick up a number like “1950.” Now, imagine that you are given a tentative range of years to answer. Research shows that people who are given a range of 1200 to 2000 actually answer with lower numbers than those who are given a range of 1900 to 2000. Respondents seem to use

the range as a tentative response (anchor) and adjust their judgment away from it. The anchoring effect has been extensively studied in consumer behavior. For example, arbitrary numbers (i.e., the last digits of the participants' social security numbers) can act as anchors to affect the amount of money that participants are willing to pay in exchange for a series of items (Ariely et al. 2003).

A further elaboration of the heuristics approach is the dual-system theory of human cognition (Kahneman 2013). According to this theory, the mind has two working modes: System I is fast, intuitive, heuristics-based, automatic, and frugal, whereas System II is slow, rational, optimality oriented, and resource-greedy. People perform many everyday tasks under System I: when the task is easy, when we need a quick solution, or when an approximate solution (not optimal) is good enough. However, certain task demands can activate System II. For instance, manipulations that reduce cognitive fluency, such as presenting the problem in a nonnative language, can lead to more thoughtful, rational, and bias-free solutions (Costa et al. 2014).

## An Evolutionary Perspective

A complementary line of research focused on understanding why cognitive biases appeared in first place in the evolution course, by analyzing their associated benefits. Thus, the error-management-theory (Haselton and Nettle 2006) proposes that cognitive biases (produced by heuristics or by any other mechanism) were selected by evolution because they actually offer advantage for survival.

In ancestral environments, there is a pressure to make important, life-or-death decisions quickly (e.g., it is better to run away upon sighting a potential predator than to wait until it is clearly visible, but perhaps too close to escape). These conditions foster the development of decision mechanisms that (a) work fast and (b) produce the so-called "least costly mistake." In this example, it is better to mistakenly conclude that a predator is in the surroundings than the alternative, i.e., mistakenly conclude that there is no predator. We know this because the two errors

have very different consequences (it could be unnecessary waste of time in the former case and death in the latter) (Blanco 2016). Sometimes the least costly mistake is the less likely mistake, as it happens with the Muller-Lyer illusion above: most of times that we interpret colliding lines as three-dimensional vertexes, and as a cue to depth perception, we are right. In general, many cognitive biases seem to systematically favor the conclusion that aligns with the least-costly mistake, formulated in any of these ways.

Additionally, exhibiting certain cognitive biases can even produce other type of benefits, particularly in emotional terms. For example, one well-known cognitive bias is the illusion of control (Langer 1975), which consists of the mistaken belief that one can exert control over outcomes that are actually uncontrollable. The emotional consequences of this bias are noteworthy: a person who thinks that there is nothing that one can do to affect a relevant outcome might feel despair, or even depressed, for it is a sad realization that one has no control over his/her life. In contrast, those who develop the illusion of control (incorrectly) attribute to themselves any positive outcome that may happen, so they feel confident and safe. Furthermore, they will even feel motivated to keep trying and producing actions to affect the environment (i.e., the illusion of control produces behavioral persistence). In fact, evidence suggests that mildly depressed people are less likely to show the illusion of control (i.e., the depressive realism effect, Alloy and Abramson 1979), which highlights the connection between cognitive biases and positive emotions.

In sum, at least some cognitive biases (like the illusion of control) seem to be associated to positive outcomes, or to the long-run minimization of costly mistakes, that could have represented an evolutionary advantage for our ancestors. Therefore, the traits that underlie the bias would have been selected through our evolutionary history.

Nonetheless, the error management theory has been received with some skepticism. Admittedly, typical cognitive biases not always align with the least-costly mistake. For instance, the same bias that facilitates the quick detection of a hidden

predator (e.g., clustering illusion), thus protecting us from a serious threat, could also produce dangerous decisions in a different context, such as believing that a bogus health treatment, such as quackery, works (Blanco 2016).

## Conclusions

Cognitive biases have been defined as a general feature of cognition. As such, they are pervasive and can be observed in a vast variety of domains and tasks. Much has been studied about the impact of these biases on several key aspects of life. For example, cognitive biases could underlie highly societal issues, such as prejudice and racial hate (Hamilton and Gifford 1976), paranormal belief, or pseudomedicine usage (Blanco 2016), and more generally, the prevalence of poor decisions in many contexts, like consumer behavior (Ariely 2008).

Thus, it is not strange that researchers have tried to find out ways to overcome cognitive biases, a practice commonly known as “debiasing” (Larrick 2004; Lewandowsky et al. 2012). Different strategies have been used to develop debiasing techniques. Some are based on increasing the motivation to perform well (under the assumption that people can use normative strategies when solving tasks). Others focus on providing normative strategies to participants, so that they can replace their intuitive (and imperfect) approaches to a problem. Finally, other debiasing interventions take the form of workshops to improve critical thinking and reasoning skills.

One common obstacle that debiasing efforts have encountered is called the “blind spot bias” (Pronin et al. 2002): While people can readily identify biases in others’ arguments, they find it difficult to detect similar biases in their own judgment. This is why transmitting the scientific knowledge about how cognitive biases work (and which factors affect them) can be a useful tool to complement debiasing strategies. In sum, advancing in our understanding of cognitive biases is in the interest of all society (Lilienfeld et al. 2009).

Optimal experience

## Definitions of Flow

Flow is a predominantly cognitive state of deep concentration and task absorption that makes a person feel one with the activity. Mihaly Csikszentmihalyi (1975/2000) identified flow in the early 1970s by interviewing surgeons, rock climbers, composers, dancers, chess players, and athletes and asking them to report their experience

when they engaged in the most challenging phases of their preferred endeavors. The interviews produced rich textual descriptions that shared six main themes: (1) focused *concentration* on the present activity, with centering of attention on a narrow stimulus field (e.g., “When I start, I really do shut out the world”), (2) *merging of action and awareness* (e.g., “I am so involved in what I am doing. . . I don’t see myself as separate from what I am doing”), (3) *loss of self-consciousness* (e.g., “I am less aware of myself and my problems”), (4) *sense of control* over one’s own actions (e.g., “I feel immensely strong”), (5) *unambiguous feedback* from the activity (e.g., “You don’t feel you have all sorts of different kinds of demands, often conflicting, upon you”), and (6) *autotelic experience*, that is, the sense that the activity is an end in itself, and hence runs independently of external rewards (e.g., “The act of writing justifies poetry”). Csikszentmihalyi named “flow” the simultaneous presence of these six components. Subsequently, Jackson and Csikszentmihalyi (1999) added three components to the definition of flow: *dynamic balance between challenge and skill* (e.g., “I feel just the right amount of challenge”), *clear proximal goals* (e.g., “I know what I have to do each step of the way”), and *loss of time-awareness or time acceleration* (e.g., “I don’t notice time passing”).

Dietrich (2004) has advanced the *hypo-frontality theory* to explain the effortless information processing that characterizes flow. The theory postulates the existence of two neural systems. The *explicit system* exerts the higher cognitive functions grounded in the frontal and medial temporal lobes, whereas the *implicit system* exerts the skill-based functions grounded in the basal ganglia. The former fosters cognitive flexibility, whereas the latter fosters efficiency. Based on the distinct functions of the two systems, flow would be a period during which a skill that has been acquired, practiced, and consolidated in the implicit system is deployed by the explicit system with no interference from the implicit system. The temporary suppression of communication between the frontal lobe and other regions of the brain can explain a number of components of flow,

such as the loss of self-consciousness and time-awareness.

There is an ongoing debate (see review by Swann et al. 2012) on two interlinked issues: (a) the set of components of flow, and (b) the separation between components of flow and other variables that may be functionally related to flow but are not indicators of flow. Regarding the first issue, positions range from assuming only one component of flow to assuming all above-listed nine components. Regarding the second issue, there are more than thirty definitional models of flow, each proposing a somewhat different partition of the nine components into antecedents of flow (i.e., factors that make flow more likely to occur or more intense), expressions of flow (i.e., components of flow), and effects of flow (i.e., consequences of having experienced flow).

## Models of Flow

The original flow model (Csikszentmihalyi 1975/2000) assumes that at any point in time of a challenging endeavor (e.g., an expert doctor performing a surgery or a chess master playing a tournament game), people assess the perceived challenges from the activity and the perceived skills in carrying out the activity, and update their perceptions depending on how well the activity is going. The model partitions the experience in the endeavor in three possible states – flow, anxiety, and boredom – that are represented as nonoverlapping areas of a challenge by skill Cartesian space. Flow occurs when there is an equivalent ratio of perceived challenges from the activity to perceived skills in carrying out the activity. Anxiety occurs when the perceived challenges from the activity exceed the perceived skills in carrying out the activity, whereas boredom occurs when the perceived skills in carrying out the activity exceed the perceived challenges from the activity. The model posits that the flow state is more likely to occur and is more intense when there is an equivalent ratio of perceived challenges from the activity to perceived skills in carrying out the activity, and both variables are high.

In the past two decades, researchers have modeled daily variations of subjective experience (e.g., concentration and absorption) over perceived challenges and skills as a linear process, and found robust support for the hypothesis that the balance of challenges and skills is key to flow, particularly in achievement contexts (e.g., Moneta and Csikszentmihalyi 1996). More recently, Ceja and Navarro (2012) argued that the variations of subjective experience at work – and hence the occurrence of flow – conform to *nonlinear dynamic models* and provided empirical evidence in support of their claim. Linear models assume that the change of outcome variables (e.g., concentration and absorption) as a function of the change of predictor variables (i.e., challenges, skills, and their relative balance) is smooth and continuous. In contrast, nonlinear models assume that as the system (i.e., the worker) departs from an equilibrium point its behavior will become increasingly unstable and turbulent to the extent that change in the outcome variable as a function of the predictor variables becomes abrupt and discontinuous. The simplest instance of such abrupt changes is provided by Ceja and Navarro's (2012) *cusp catastrophe model of flow*. The model states that the progress from a high-challenge/low-skill state to the high-challenge/high-skill state (i.e., the “flow zone”) is so turbulent that a minimal fluctuation of the levels of challenges and skills may result in either a sharp enhancement of subjective experience or a sharp deterioration of subjective experience, and the probability of either outcome is about 50%. This means that the path to the flow state is an inherently unstable process that could fail abruptly. Therefore, achieving flow at work comes at the cost of great variability of outcomes.

## Universality of Flow

The Flow Questionnaire (FQ; Csikszentmihalyi and Csikszentmihalyi 1988) was the first attempt to measure flow (for other measurement methods see Engeser 2012, and Fullagar and Delle Fave 2017). The FQ presents some of the most insightful descriptions of flow that emerged through

interviews and asks respondents whether they have ever had similar experiences. Research using the FQ in diverse samples – including blind nuns, former drug addicts, members of alpine communities, and professional surfers – from a wide range of cultures has shown that flow is a universal experience, although the specific activities that foster flow are shaped by culture and hence differ somewhat across cultures. Moreover, in all cultures flow is more likely to occur in work or structured leisure activities.

Flow was originally identified and operationalized as a state. Researchers have then conceptualized and operationalized flow also as a broad disposition, meant as the tendency to experience flow frequently and intensely across a wide range of situations, and as a domain-specific disposition meant as the tendency to experience flow frequently and intensely in a specific context such as work, study, or sports (Jackson and Eklund 2002). When measured as a state, a small percentage of respondents report never having experienced flow. When measured as a domain-specific disposition in twin studies, the heritability estimate of flow proneness is moderate in the domains of work, maintenance, and leisure and is explained by the same genetic factors across the three domains (Mosing et al. 2012). This implies that not all individuals will experience flow, and if the environmental opportunities and personal competencies/skills for flow exist, the more genetically predisposed individuals will be more likely to experience flow.

## Antecedents and Consequences of Flow

Individuals who are predisposed for experiencing flow also tend to have personality traits such as low *neuroticism* (i.e., a tendency to experience anxiety, moodiness, depression, vulnerability, and self-consciousness), high *conscientiousness* (i.e., a tendency to be self-disciplined, self-organized, hardworking, and “down to earth”), high *openness to experience* (i.e., a tendency toward unconventionality, intellectual curiosity, imaginativeness, aesthetic sensitivity, cognitive/emotional differentiation, and engagement of

experience), and *internal locus of control* (i.e., a tendency to believe that rewards and punishments are contingent on one's behavior) (Mosing et al. 2012). However, flow proneness is not associated with *intelligence* (Mosing et al. 2012).

Frequent and intense flow experiences are associated with better adaptation, coping, and subjective well-being across the life span (see reviews in Engeser 2012). Flow at work has been investigated across a wide range of occupations and organizational contexts, including scientists, medical doctors, software engineers, and school teachers (see reviews in Fullagar and Delle Fave 2017). The tendency to experience flow at work results in enhanced employee's psychological well-being and enhanced job performance, in general, and creative contributions to work, in particular. However, the link between flow and work performance is present only for individuals with high *achievement motivation* (i.e., a tendency to seek success in competition with a standard of excellence). In particular, only highly motivated employees utilize the flow zone (the combination of high challenge and high skill) to enter flow, and utilize flow to enhance performance.

## Directions for Future Research

Even though numerous traits have been linked with the occurrence of flow, a key question is still insufficiently addressed: Can one make flow happen at will? From the beginning, Csikszentmihalyi (1975/2000) postulated the existence of an "autotelic personality," one that pursues an activity purely because it is intrinsically rewarding. This personality was theorized to possess "metaskills," such as curiosity and persistence, which would enable the self-regulation (e.g., starting, sustaining, and modulating) of flow. Swann et al. (2012) conducted a systematic literature review of flow in elite athletes and estimated that 66–72% of athletes perceived flow to be controllable and useful for coping with the challenges of the competition. Recently, Wilson and Moneta (2016) developed and validated a questionnaire measuring *flow metacognitions* (i.e., people's awareness of and beliefs about the

flow state and its consequences, and about strategies for achieving and maintaining flow) and found that these allow employees to self-regulate flow at work. Because metacognitions have been shown to be modifiable through metacognitive interventions, this research development opens the possibility to coach individuals to use flow as a way of coping with demanding situations.

Even though flow was originally discovered as a solitary experience (Csikszentmihalyi 1975/2000), researchers have more recently found instances of "social flow," in which two or more interacting individuals experience interlinked forms of flow. For example, a crossover of flow between music teachers and their students was observed, which mimics the pattern of *emotional contagion* (e.g., an automatic tendency to converge emotionally). Moreover, the observation of jazz ensembles, improv theater groups, sport teams, and creative business teams has revealed that teams can develop and maintain "team flow" for the duration of a collective endeavor, and by capitalizing on continued team flow tend to produce more creative team output. These observations indicate that collective flow is highly enjoyable and builds up psychological resources at least as much as individual flow does. However, research has to date operationalized team flow simply as the sum of the individual flow states experienced by the members of the team and has hence ignored team-system dynamics. Future research should, therefore, examine the case of "autotelic teams," wherein team members feed each other to build the experience of flow interactively.

Finally, the construct of flow has been utilized to explain disruption of natural behavior in animals. In particular, it has been suggested that captivity may prevent the flow of behaviors that animals are motivated to perform, and eventually lead animals to disengage from their environment, experience a chronic state of boredom, and lose versatility of behavior and adaptability to the environment. Whether flow can be achieved in absence of metacognitions that can be verbalized is an open question that could be answered only by comparing flow-like neurophysiologic patterns in humans and animals. As neurophysiologic measures of flow keep being developed and

validated, future research will be able to evaluate the similarity of flow in humans and animals and possibly extend flow theory and its applications to animals.

## Cognitive Imitation

Francys Subiaul

George Washington University, Washington, DC, USA

## Synonyms

[Imitation](#); [Non-motor imitation](#); [Observational learning](#); [Social learning](#)

## Definition

**Cognitive imitation** is a type of social learning; specifically, a subtype of imitation that involves copying abstract – inferred – rules rather than observed – concrete – motor or oral responses.

## Introduction

Cognitive imitation is typically contrasted with other subtypes of imitation including, motor and

vocal or oral imitation. Like all forms of imitation, cognitive imitation involves vicariously learning and replicating specific abstract rules inferred from observation. The main difference between cognitive motor imitation, for example, is that whereas in the typical imitation learning experiment, subjects must copy representations of novel responses or sequences of specific actions (novel motor imitation), and in a novel cognitive imitation paradigm, subjects have to learn and copy abstract representations or rules. In such a paradigm, while the actions themselves may be familiar (e.g., pressing a button), the rule organizing those actions is new.

The following example illustrates the difference between cognitive and motor imitation: Imagine someone overlooking someone's shoulder and stealing their automated teller machine (ATM) password. As with all forms of imitation, in this example, the thief learns and successfully reproduces the observed sequence. The thief in our example, like most of us, presumably knows how to operate an ATM. As such, the actions associated with operating an ATM isn't what the thief is learning (or copying). Instead, the thief is likely to learn and copy one of two abstract rules: spatial or cognitive. For example, the thief may learn and subsequently copy the following spatial rule: touch the button in the bottom left, followed by button on the bottom right, then the button in the top right, and finally the one in the middle. This would be an example of motor-spatial imitation, because the thief's response is guided by an observed spatial rule. Alternatively, the thief may ignore the spatial patterning of the observed responses and instead focus on the particular markings on buttons (i.e., numbers) that were touched, generating the following abstract numerical (cognitive) rule: 7-9-3-5. Vicariously learning and reproducing this unobserved (inferred) rule to guide their response would be an example of cognitive imitation. Of course, this is not an ideal example because, in fact, unless you ask the thief, you would not know if they used a spatial or cognitive rule given that the numbers are in the same location with every attempt. However, if the numbers appeared in a new position every time you tried to enter the password – the thief using a cognitive rule would, nonetheless, reproduce the target password.

## Cognitive Imitation in Rhesus Monkeys

The term “cognitive imitation” was first introduced by Subiaul and his colleagues (Subiaul et al. 2004). In their original paper, they defined cognitive imitation as “a type of observational learning in which a naïve student copies an expert's use of a rule.” To isolate cognitive from motor imitation, Subiaul and colleagues trained two rhesus macaques to respond, in a prescribed order, to different sets of photographs (serial lists) that were displayed simultaneously on a touch-sensitive monitor. The position of the photographs varied randomly from trial to trial, preventing subjects from learning a series of motor-spatial responses (Terrace 2005). Both monkeys learned new sequences more rapidly after observing an expert monkey execute those sequences than when they had to learn new sequences entirely by trial and error. A microanalysis of each monkeys' performance showed that each monkey learned the order of two of the four photographs faster than baseline levels. A second experiment ruled out social facilitation as an explanation for these results. A third experiment demonstrated that monkeys did not learn when the computer highlighted each picture in the correct sequence in the absence of a monkey (“ghost control”), which suggests that monkeys, in contrast to human children (Hopper 2010; Subiaul et al. 2007, 2011), require an agent to motivate social learning.

## Cognitive Versus Motor-Spatial Imitation

Subiaul et al. (2012), using two computerized tasks that measure the learning of two abstract rules: cognitive rules (e.g., apple-boy-cat) and motor-spatial-based rules (e.g., up-down-right), have shown that there are important dissociations between the imitation of these two types of rules. Specifically, results have shown that while 3-year-olds successfully imitate cognitive rules, these same 3-year-olds fail to imitate motor-spatial rules (Subiaul et al. 2012). This dissociation is not because there is something inherently harder about learning spatial versus cognitive rules. A series of follow-up studies showed that

3-year-olds correctly recall spatial rules learned by trial and error following a 30s delay (Exp. 2). This result demonstrates that 3-year-olds' motor-spatial imitation problems are not due to difficulty learning new spatial rules in general. But perhaps, 3-year-olds have a problem learning vicariously from a model. To test this hypothesis, a follow-up study had 3-year-olds observe a model correctly touch the first item (e.g., Top Right) in the sequence, but then skip the middle item (e.g., top left picture) and, instead, touch the last item in the sequence (e.g., bottom left picture), resulting in an error. Upon making this error, the model said, "Whoops! That's not right!" This highlighted that the error was unintentional. This is a goal emulation learning condition, as the child has to copy the model's intended goal (top-right, bottom-left, top-left), rather than the observed (incorrect) response (top-right, top-left). In this study, 3-year-olds generated the intended (rather than the observed) sequence (Exp. 3). Three-year-old's success in the goal emulation condition excludes the possibility that 3-year-olds' motor-spatial imitation problem is due to difficulty vicariously learning (i.e., because of a lack of interest, failure to attend, problems inferring goals, etc.) a novel spatial rule from a model. Children's success in the goal emulation condition suggests that social learning may be achieved by social reasoning (inferring goals) and causal inferences (error detection), independently of any domain-specific imitation learning mechanism.

### Domain-Specificity in Imitation Learning

To further explore this dissociation between cognitive- and motor-spatial imitations, Subiaul et al. (2015) tested preschoolers (2–6 years) on a variety of learning conditions using the cognitive and motor-spatial tasks. Results demonstrated that there was no significant relationship between imitation in the cognitive and the motor-spatial task. Analyses showed that only age predicted improved imitation performance in each task. Moreover, children's ability to individually learn in each task by trial and error did not predict their ability to imitate those same rules in either task.

However, goal emulation in the motor-spatial task did predict imitation learning in the same task. This result is surprising because, children can infer the spatial rules from a model's error before they can imitate spatial rules (Subiaul et al. 2012: Exp. 3). The association between goal emulation and imitation in the motor-spatial tasks suggests that goal emulation scaffolds the development of imitation in the motor-spatial domain, but critically, it does not seem to do so in the cognitive domain. These patterns of results support the hypothesis that distinct cognitive processes underlie cognitive versus motor-spatial imitation.

## Cognitive Impenetrability

Michael R.W. Dawson

Department of Psychology, University of Alberta,  
Edmonton, AB, Canada

### Definition

Cognitive impenetrability is a property of the basic information processes of cognition. If a process is cognitively impenetrable, then the operation of this process cannot be altered by changing the contents of mental representations (i.e., an agent's beliefs, desires, or goals). This is because the process is “wired in” and its operation must be explained by appealing to neuroscience.

### Introduction

Six decades after experimental psychology's cognitive revolution, it is now commonplace to find studies of animal cognition. In general, the term “cognition” is synonymous to “information processing.” Thus, theories of animal cognition are theories about how animals process information. However, cognitive theories also carry more technical and specific requirements. In particular, a cognitive theory distinguishes between the contents of mental representations and the information processing mechanisms that manipulate these contents. The core information processing mechanisms of cognition are called the cognitive *architecture* (Pylyshyn 1984). Pylyshyn (p. 30) defines the cognitive architecture as “the basic operations for storing and retrieving symbols, comparing them, treating them differently as a function of how they are stored (hence, as a function of whether they represent beliefs or goals), and so

on, as well as such basic resources and constraints of the system, as a limited memory.”

## Wired Cognition and Cognitive Impenetrability

One of the key characteristics of the cognitive architecture is that it is presumed to be largely innate, relatively permanent, and directly implemented by neural processes. That is, the architecture defines the properties of what has been called “wired cognition” (Magnani 2009). This is a fundamentally important property, because explaining the functioning of a component of the cognitive architecture requires an account of how the brain implements this component. Thus, by ultimately grounding a cognitive theory in an architecture, one converts a cognitive description into a cognitive explanation (Dawson 2013). The architecture is the bridge between cognition and the brain. As a result, for their cognitive theories to be explanations, researchers must identify the cognitive architecture.

## The Cognitive Penetrability Criterion

How does one defend the claim that some cognitive function is part of the architecture? One methodology, the *cognitive penetrability criterion*, is inspired by the architecture's “wired-in” nature (Pylyshyn 1984, 1999). If a function is part of the architecture, then it will not be affected by changes in cognitive content – changing beliefs should not result in a changing architecture. This means that the architecture is *cognitively impenetrable*. In contrast, if changes in cognitive content produce changes in the operation of the function, then the function is *cognitively penetrable*. “If a system is cognitively penetrable then the function it computes is sensitive, in a semantically coherent way, to the organism's goals and beliefs, that is, it can be altered in a way that bears some logical relation to what the person knows” (Pylyshyn 1999, p. 343). The architecture is *not* cognitively penetrable. Finding that a function is cognitively penetrable indicates that it is *not* part of the architecture.

In studies of human cognition, the cognitive penetrability criterion is used to validate claims that particular functions belong to the architecture. In general, this involves observing the operation of the function, then changing a belief that is semantically related to the function, and finally determining whether the operation of the function changes. If it changes in a fashion that is semantically linked to the changed belief, then the function is cognitively penetrable and is not part of the architecture. This paradigm has been used to challenge the claim that certain operations on mental images, like scanning, are not part of the architecture (Pylyshyn 1984). The cognitive penetrability criterion has also been used in the study of apparent motion to show that the processes that track the identities of objects in apparent motion are likely part of the architecture because they are not affected by changes in beliefs about whether objects are moving in depth or not (Wright and Dawson 1994). However, Wright and Dawson also show the processes that create the appearance of an object in illusory motion can be penetrated by beliefs about depth of movement and therefore are not part of the architecture.

Of course, the cognitive penetrability criterion is much easier to apply in the study of human cognition than it is in the study of animal cognition. This is because it is much harder to verify than one has manipulated the beliefs of animal subjects. However, animal investigations that parallel human experiments are possible. For instance, studies that support the claim that a particular animal behavior is controlled by instinct (and not by higher-order processing) help establish that the behavior is controlled by the architecture, given the view that instincts are examples of wired cognition (Magnani 2009).

Consider one notable example from the study of nest building by wasps. Ethologist W.H. Thorpe reviewed studies of nest building in a variety of animals, including wasps, and proposed that nest construction behaviors were controlled by an *ideal releaser* (Thorpe 1963). An ideal releaser serves the role of a cognitive representation. “The bird must have some ‘conception’ of what the completed nest should look like, and some sort of ‘conception’ that the

addition of a piece of moss or lichen here and here will be a step towards the ‘ideal’ pattern, and that other pieces there and there would detract from it” (Thorpe 1963, p. 22). With this type of theory, one would hypothesize that small damage to a physical nest, making it slightly different from the mentally represented ideal releaser, would produce behaviors that simply repair the damage to make the actual agree with the desired mental content.

However, this hypothesis is not confirmed by the behavior of the mud wasp *Paralastor* (Smith 1978). This wasp builds its nest by digging a hole in the ground, lining the hole with mud, and then building an elaborate funnel on top of the hole to keep parasites out. The funnel is a long straight tube, to which is added a marked curve; a large bell-shaped opening is attached to the end of the curve. Smith created a hole in the curve that the wasp added to the straight tube. Instead of causing the wasp to simply patch the hole as might be expected from the ideal releaser theory, this instead led the wasp to create a brand-new tube out from the hole in the curve, producing a second funnel structure built on top of the first. The irrationality of this behavior can be taken as evidence that this wasp’s nest building is cognitively impenetrable, part of the animal’s architecture, and best explained by appealing to sequences of instincts governed by stigmergy (Karsai 1999).

Researchers in animal cognition have access to other methodologies for supporting claims that particular processes are part of the architecture. These too rely on the assumption that if a process is cognitively impenetrable, then it is directly implemented by the brain; it is wired cognition. Thus, any techniques that can elucidate the neural mechanisms that instantiate specific information processing can be used to argue that this processing is cognitively impenetrable and is part of the architecture.

For instance, it has long been argued that a great deal of early human visual processing is cognitively impenetrable (Pylyshyn 1999), and this hypothesis is typically supported by grounding computational or cognitive models of visual perception in the neural circuitry of early vision (Marr 1982). This evidence is largely the product

of single-cell recording studies of animal brains. A variety of methods exist for studying how the brain implements many other cognitive processes, including learning, memory, and navigation (Kandel et al. 2013). It is reasonable to predict that this kind of evidence will more likely be used in the future to map the architecture of animal cognition than will be evidence collected using animal analogs of the cognitive penetrability criterion.

## Cognitive Map

Ken Cheng

Department of Biological Sciences, Macquarie University, Sydney, NSW, Australia

The notion of *cognitive map* has a more general meaning as a metaphor for relations in the experiences of life and a more specific meaning in terms of cognition of relations among spatial attributes. The general term was made famous by the American learning theorist Edward Tolman (1886–1959), who formulated the term *cognitive map* to mean cognition of relational aspects of experience (Tolman 1948). This term has seen a revival in the last decade, as a region of the brain intimately connected with spatial cognition, the hippocampus, was found to code another fundamental dimension of experience, that of time. The spatial meaning of the term cognitive map received a boost with the discovery of neurons in the hippocampus of rats that fire the most when the rat was at a particular place in its environment, an arena in a lab. This discovery of what are called *place cells* is attributed to behavioral neuroscientist John O’Keefe. The spatial notion, discussed most in rats, humans, and honeybees, continues to attract debate and controversy.

## Tolman’s Cognitive Map

While the examples that Tolman (1948) discussed in his famous paper on the cognitive map concerned movements of rats in space, his writing also made it clear that the notion was more general. Tolman (1948) wrote of the brain that “the central office is far more like a map control room than it is like an old-fashioned telephone exchange” (p. 192). Tolman reported that rats learn about what is where in space from exploring space without any motive to obtain anything. In one case, sated and un-thirsty rats wandered a Y-shaped maze and learned that water was in one arm while food was in a second arm. Later,

when the rats were made thirsty, they went to the water-containing arm on the very first trial, while hungry rats headed to the food-provisioning arm from the first trial. Work in Tolman's lab also showed that rats could learn the layout of a complex maze from wandering the maze for ten sessions without any rewards. Once these hungry rats found food at the exit of the maze on day 11, they made haste to wind their way to the exit the very next trial – they were if anything faster than rats that had been rewarded with food every time they found the exit of the maze – showing that they had learned the layout of the maze without reward, a phenomenon called *latent learning*.

Tolman thought that hesitant behavior in rats deciding which direction to take at a junction reflected the learning of spatial relations, the building of their cognitive map. Such hesitant looking behaviors are called vicarious trial and error. Systematic patterns of travel through a maze were thought to reflect a nonverbal form of hypothesis testing. If all the data on rats had not made the notion of cognitive map wide ranging enough, Tolman then wrote about various clinical and social phenomena in human behavior, such as fixations or displacement of aggression onto outgroups (Tolman 1948). It is clear that the cognitive map encompassed many aspects of life's experiences.

The nature of Tolman's cognitive map was left unclear. Even in its spatial sense, it was unclear what kinds of spatial relations were encoded. Only something of the connections between places was supposed. Perhaps one shortcut experiment suggested encoding of directions, although the study has been much criticized. In the starburst maze experiment, rats were trained to run a dog-legged path with three turns in it along a well-defined track to arrive at a goal. On a test, the usual path was blocked, with the rest of the maze transformed into an array of radiating tracks spreading from the central start platform. Most rats chose the track whose direction pointed most directly to the goal location. It is unclear from the experiment, however, what the rats had learned about the spatial properties of the set up. Instead of some map-like representation of the set up, they might have learned to aim at a

particular landmark located at the goal. Such a strategy of beaconing would not be considered as equivalent to using a cognitive map. Tolman wrote, again metaphorically, of narrow strip maps and comprehensive maps. The metric and Euclidean nature of the cognitive map only bloomed in the 1970s.

## Metric Cognitive Map

The term *metric* hails from formal geometry, meaning distances, angles, and directions, the properties that pop to mind most readily in intuitions of geometry. Metric properties make the stuff of Euclidean geometry, the typical geometry high school students would learn, perhaps in its algebraic form as Cartesian  $x$ - $y$  coordinates as well as the geometry of lines and points. A metric cognitive map was explicitly proposed in a classic and much cited book in 1978, *The Hippocampus as a Cognitive Map* (O'Keefe and Nadel 1978). Freely mixing philosophy of mind, neuroscience, and psychology, O'Keefe and Nadel (1978) likened the spatial representation of rats to having a topographic map of the environment.

A topographic map allows the traveler to plan a route of travel, to deal with unexpected obstacles, or to reorient after displacement. O'Keefe and Nadel (1978) called navigation using a cognitive map the *locale* system. The rat was said to possess as well a more route-like system of navigation called the *taxon* system. Using the taxon system is akin to following instructions cooed by the voice of the navigation aid in some cars, such as in 500 m, turn left onto X street. Or it could be like following the kind of route instructions scribbled on paper, such as go down X street; at the gas station, make a left turn; go to the next traffic light, then turn right. ... More formally, the taxon system consists of a to-do list for encountered stimulus situations. Gas stations and traffic lights define stimulus conditions; left and right turns define what to do. A rat might learn, more example, to turn left at the first junction of a maze from the start point, or to turn right when it encounters a white card on the wall.

The role of the hippocampus, as might be expected from O'Keefe and Nadel's (1978) title, is to subserve the locale system. O'Keefe is most famous for discovering neurons in the rat's hippocampus that fire the most when the rat is at a particular place in space, irrespective of how it got there or which way it is facing, the aforementioned *place cells*. O'Keefe won a share of the Nobel Prize in Physiology or Medicine for his work in 2014.

While place cells suggest suitable neurophysiology for encoding a map-like representation of space, it was unclear what characteristics the rat learns about space. In particular, it was unclear whether any metric properties were encoded. Gallistel (1990), in two substantial chapters in his influential book, suggested that many animals in fact encode metric properties. Spatial achievements that Gallistel wrote about included hoverflies that return repeatedly after excursions to just about the same point in midair, a location quite aptly described as the middle of nowhere. Gobies in tide pools sometimes find themselves in an isolated pool when the water level sinks low enough to create separated pools of water. The gobies can use some information of the topography to jump from one isolated pool in the direction of another pool. Gallistel devoted most pages, however, to the encoding of metric properties in the rat.

The study in question was one of this author's (Cheng 1986). The key clue to the use of metric properties was a curious mistake that rats often make in a rectangular-shaped arena (Fig. 1). In searching for buried sweet treats, the rodents would confuse diagonally opposite locations, a confusion called the rotational error. They did this even when many cues other than the shape of the arena, such as smells in the corner and different colored walls, disambiguated this mistaken rotational error from the correct goal. To make the rotational error, the distances and directions from surfaces had to be correct, although the relation to what can be called non-geometric cues, such as the nature of smells or the color of the surface, was incorrect. It was as if they had encoded distances and directions from walls and used only that information to locate the booty. In

**Cognitive Map, Fig. 1** Schematic depiction of the rotational error found in rats (Cheng 1986). Rats were searching for buried food in a rectangular dish, for example, at the location labeled “goal.” The goal location, to which they had been previously exposed, changed from trial to trial. Rats would often commit the error called the rotational error, at 180° rotation from the goal through the center of the space. Many disambiguating cues were arrayed around the walls, including different brightness levels (*white* vs. *black*), distinct panels in the corners (not shown), and distinct smells emanating from two corners. In making the rotational error, the rats were correct with respect to the overall shape (metric properties) of the space, but incorrect with respect to all the features (e.g., long gray wall) arrayed on the shape, colors, textures, and smells

later years, different interpretations of such studies on geometry emerged. For instance, the rat might be matching a panoramic view based on where major vertical and horizontal edges in space are. The hypothesis that the rat encodes distances and directions, metric properties, however, is commonly held.

Gallistel's (1990) conception of a cognitive map was encompassing. Any encoding of spatial relations amounted to a cognitive map. In a rectangular arena, the rat hardly travels anywhere: it is enclosed in an arena less than two meters long, whereas in real life in the wild, this rodent would travel hundreds of meters or kilometers. In Cheng's (1986) study – which stayed away from using the controversial term *cognitive map* – the rats learned to use surrounding cues to pinpoint a place. What was missing was using a map-like representation to plan new paths of travel. The next wrinkle in the concept of a cognitive map

was that an animal should be able to deduce a new, never-before-traveled path if it possessed a cognitive map.

## Cognitive Map, Detours, and Displacements

The test for such a deductive capability based on inferences from using a cognitive map is to displace an animal and see if it finds its way back. Let us say that the goal is at G; the animal has traveled to A, perhaps a feeder where food is usually found; and experimenters swoop up our test subject, disorient it, and plunk it at a distant site B. If the animal finds its way from B to G, and we could rule out other kinds of explanations, then it is warranted to attribute a cognitive map to our test animal. Such a test is not hard to do, but these other potential explanations make complications and brew controversy about the cognitive map.

The arguments have played out the most in a much-studied insect, the honeybee (*Apis mellifera*). Foraging bees routinely find their way back home from their foraging excursions. In their natural trips – as opposed to visiting an experimentally provided feeder with a bonanza of artificial nectar in the form of sugar water – they visit multiple flowers, typically in one vicinity often called a patch in the foraging literature. After filling up, they then fly directly home. Before a worker bee heads out foraging, she – all worker bees are females – flies a number of *orientation flights* to learn about her local landscape. On many of these orientation flights, she typically zooms out in one direction and then returns directly from that direction. Across different orientation flights, the budding forager would criss-cross many different directions from her hive. Displacement experiments have been conducted on free-flying honeybees over natural terrain, but the import of the results is disputed.

Chief among the alternative explanations are *path integration* and route following based on views of the scenery. Path integration means keeping track of the straight-line distance and direction of one's total travel. The continuing output of the path integrator is a vector pointing to the starting

point (typically home), that is, a distance and direction home. When the time to fly home comes, for example, when the crop is filled with nectar, the bee could fly off the calculated vector. Bees and ants have been much studied on this capability and demonstrate it ubiquitously. If a forager has flown 100 m East to a feeder, its path integrator should indicate a vector of approximately – the path integrating process, like all biological processes, gathers errors – 100 m West. If a worker relying on path integration were displaced, it would fly 100 m West. The path integration process does not account for passive displacement, whereas a cognitive mapping process should. The traveler would recognize where it is according to the scenery at the release point and plan according to where that location is on its cognitive map. The cognitive mapping bee should fly in the release-point-to-home direction.

Most of the early observations of the initial flights of such displaced bees support the path-integration hypothesis. The displaced bee trained in the hypothetical conditions of the previous paragraph would fly west initially. A different twist to the story turned up when the animals were tracked with harmonic radar over an open field. In this technology, a tiny antenna is attached to the back of the forager, and the radar tracks her *x-y* coordinates, delivering entire paths. After displacements from a feeder, yes, their initial flights were again in the vector direction indicated by path integration, which seemed to be a strong driver of initial orientation. Interesting results then transpired: after the vector had been flown, many bees would make their way either home or to the feeder again (Menzel et al. 2005).

Not everyone accepts the results of Menzel's team as demonstrating cognitive mapping in honeybees; in fact, currently most scientists studying insect navigation are in the nay-sayer camp. Their argument is based on the other main alternative hypothesis: view-based route following. View-based navigation is well established in insects, especially in ants. Ants without any vector from path integration – and experimenters create such a state in the ant by capturing it near home, making its vector effectively zero – routinely followed well-traveled routes home. The terrestrial view is

needed for such route following: when it is blocked, orientation is typically random. Such views have a certain *catchment area*, a term indicating an area wider than the typical route in which the view-matching strategy would work to steer the navigator home. Returning to the homing of displaced honeybees, these nay-sayers argue that the bees might have learned to associate a view found at a displaced site with a direction home. Even if they had not been to a displaced location before, the location is likely within the catchment area of some views they had learned. Recall that the forager would have flown in a number of directions around her hive before heading out to forage. If view-based route behavior is already well established in ants and bees, why invoke a new map mechanism? So argue the nay-sayers in calling for parsimony.

In the current state of the science, we are left with a logical and conceptual difficulty in interpreting such displacement results. In the test field of Menzel's team, the distant skyline might well be too low to be resolved by the eyes of the honeybees. But plenty of visual patterns are found on the ground of the agricultural site, such as ditches and different textures made by different plants. Something in the visual scene – or information in some other modality, but the visual scene is the most likely source – has to be recognized by the displaced bees or else navigation is impossible. This recognition process could feed either a route-like process or a map-like process, and at present, experimental techniques have not been used to try to untangle this conundrum.

The same conundrum applies to the idea of a map on a global scale – the term *map* typically coming without the cognitive accoutrement. The best case to illustrate the route versus map contrast is with sea turtles because the best data are available. Sea turtles have been shown to use magnetic cues of the Earth for navigation on a global scale. Thus, loggerhead turtles swim around the Sargasso Sea, a safe region for them in the North Atlantic. Experiments have been done displacing turtles virtually – young ones because full-grown ones are way too heavy to handle – to a place with different magnetic conditions. That is, scientists fabricated artificial magnetic conditions around the tank in which the turtles were swimming to

simulate another location on Earth. The turtles then navigated as if they had been displaced to the actual location on Earth that was simulated. The studies provide strong evidence that magnetic cues are used for navigation by the sea turtles (Putman et al. 2011). The scientists then point out that it is unclear whether a map-like mechanism is at play or something akin to route instructions. Do the magnetic conditions allow the turtles to deduce that they are now at longitude  $x$  and latitude  $y$ , on the basis of which the best direction to swim in would be  $\theta$ , or do they note that they are now under magnetic conditions  $\alpha$  and they have learned that when under conditions  $\alpha$ , swim in direction  $\theta$ ? This conundrum also remains unresolved.

Returning to rats, experimenters have more control over the travel experiences of lab rats, albeit in small arenas and mazes. Rats have been shown to cope with displacements in a map-like fashion with simple displacements effected by enforcing a new path of travel (Fig. 2). Singer et al. (2006) trained rats to travel down the right and left arms of their simple three-arm maze. Two of those arms, including the center one, contained

**Cognitive Map, Fig. 2** Schematic sketch of the setup used by Singer et al. (2006) to demonstrate a simple cognitive map in rats (not to scale). From the start platform (*big white rectangle*) during training, the rats could travel down the three long arms, each of which had different textural cues on its surface. Food was located at the ends of the center arm and one other arm (the left arm or the right arm). The connecting arms between the goal boxes at the ends of the arms (shown in *black*) were blocked. On a test after training, the connecting arms between goal boxes were open, and the rat was forced down the center arm. The question was whether the rats would take the correct connecting arm to the goal box that usually had food during training

food; the other arm was empty. In training, the connecting arms between the central arm and the side arms were blocked. Each arm had a distinct covering to make it identifiable as a place/route. After training, a test was given on which the entrances to the side arms from the start point were blocked. The untraveled connecting arms between the central platform and the side arms were opened. The rats had to travel down the center arm to get food, and the question was then whether they would know how to turn in the direction of the side arm that had been the second arm proffering food. The rats were 75% correct on the first test trial.

The astute reader would note that a path-integrating mechanism could in principle solve this task. Say the right and center arms contained food during the training. The rat would learn a vector, say, roughly  $30^\circ$  to the right from the center of the back wall. When on a test the rat was forced to go down the center arm, it was just a matter of path integrating to the right arm after an enforced detour. Desert ants handle this kind of enforced detour on their way home routinely. That path integration alone was insufficient was shown in a separate experiment in which the arms were not distinguished by distinct textures; they all looked and felt the same. For path integration, the texture and look of the arms, the routes of travel, should not make any difference. However, under conditions of identical looking and feeling arms, the rats were at chance on the test when they were forced to travel down the center arm first. The authors concluded that the rats learned a simple cognitive map.

While path integration alone seemed insufficient for Singer et al.'s rats, this process probably plays a role in building any kind of cognitive map. Path integration could supply  $x$ - $y$  coordinates, at least approximate ones, for distinct locations relative to a starting point such as one's home. Mapping might be a process of collating such coordinates onto a common frame.

On the other hand, failures at constructing a cognitive map based on separate views of the environment have also been shown in rats (Benhamou 1996). The study had rats swimming in a round pool to find a platform hidden just under surface level. Rats can swim well, but are

averse to paddling in the water, preferring to clamber onto a platform. The key question asked of the rodents was whether they could piece together different chunks of views around the pool into some integrated whole. The views were of parts of a normal lab room, decked with posters on walls, and outfitted with an array of desks, chairs, and cupboards. During training, a marquee was placed in the pool allowing only about one quarter of the view of the room from inside it. The desired platform was inside the marquee, always in the same place in the pool and in the room. Over different phases of training, the rats got to see different parts of the room from inside the marquee. On a test, they faced yet a new view inside the marquee with the contraption now offering bits of two previous separately viewed segments. Could the rats piece all the views together to figure out how to swim directly to the platform? Over several experiments, the rats failed miserably. Benhamou (1996) called his paper *No evidence for cognitive mapping in rats*.

Despite such limits, neuroscientists generally endorse a cognitive map for rats, based largely on a huge body of work probing the coding of spatial characteristics in the hippocampal formation, the network linked intimately with the hippocampus proper. The network contains, besides the already mentioned place cells, head-direction cells, which fire the most when the rat's head is facing a particular direction, and grid cells, which fire the most over a regular triangular grid of locations, among others (Cheng and Jeffery 2017). One recent variant of the cognitive map returns to Tolman's inclusive notion of the metaphoric cognitive map (Schiller et al. 2015). It now turns out that other cells in the hippocampus are sensitive to time rather than space, cells from the same hippocampal population. These cells fire the most at particular points in a sequence of events. The hippocampus then is thought to support a Tolmanian map that incorporates spatial, temporal, and likely other fundamental dimensions of experience.

In the studies addressing the rat's cognitive map, or spatial cognition in general, the spaces are tiny relative to the natural travel of rats. When released on a small rat-free island, male rats would wander all over the terrain, covering hundreds and

hundreds of meters. (Only males were released to ensure that no rat population would be established should the test animals evade trapping.) No studies have investigated their navigational mechanisms over such natural scales. In a classic study of wild rats in a suburban enclosure (Calhoun 1963), the rats established many routes around the enclosure and traveled much on routes. Far more studies of rats traveling on natural scales are needed to understand their navigation.

This piece on the controversy of the cognitive map will end with humans. Surely, big-brained *Homo sapiens* would possess cognitive maps, right? Even with humans, however, the case is less than clear-cut. Our metric estimates of space are often distorted and error-prone. One recent study using virtual realities shows that gross violations of the fundamental tenets of metric properties go mostly undetected by adult humans (Warren et al. 2017). The space was virtual: subjects donned immersive goggles that created their visual world. Virtual technology allowed tricks such as sudden displacements of subjects to be enacted without touching subjects at all, something impossible to do in physical space. In the crucial manipulation, the virtual worlds contained *wormholes*: when a traveler arrived at the middle of one wall in the square space, for example, she suddenly found herself at the middle of another wall, a 90° turn away. Subjects learned the object locations in the un-Euclidean wormhole-infested space just fine, as well as in a perfectly Euclidean wormholeless space. They used wormholes readily for routes and shortcuts, and only one participant mentioned anything strange about the wormhole-infested space.

The upshot was that Warren and coauthors suggested that humans encode a cognitive graph rather than a metric cognitive map. A graph contains knowledge of route connections between nodes on the map. It also contains rough local metric knowledge such as angles of junctions or distance to the next node. It allows some shortcutting and route planning, but falls far short of a globally consistent frame on which locations are plotted in *x-y* coordinates, an ideal of a metric cognitive map, the kind of topographic maps O’Keef and Nadel (1978) envisaged.

All in all, the notion of a cognitive map remains controversial for all navigating species, from insects to humans. Evidence for a metric cognitive map is disputed in all species discussed in this entry. Whether more clarity will emerge in the coming years remains to be seen.

## Cognitivism

Eric Sidel  
Philosophy Department, The George Washington  
University, Washington, DC, USA

Cognitivism in the study of nonhuman animal minds is the research area that presupposes that the behavior of nonhuman animals is sometimes best explained with reference to their internal cognitive states. Such states are often thought to be structured representations that are semantically evaluable (i.e., true or false, satisfied or unsatisfied). Cognitive explanations accordingly

involve computational processes that operate on these structured representations. These explanations are offered of phenomena that involve information processing, such as learning, memory, communication, problem solving, and tool use (Greenwood 1999). Cognitive explanations are *mental* explanations inasmuch as the dominant paradigm since the so-called cognitive revolution holds that the mind is a manipulator of representations. This description may remind the reader of the contemporary digital computer. As we shall see, this metaphor is not accidental but is instead central to the cognitivist paradigm.

One cannot properly understand cognitivism in the study of nonhuman animal minds (hereafter: “animal”) without understanding the cognitive revolution in psychology, and one cannot understand the cognitive revolution in psychology without understanding behaviorism, the received view against which cognitivism rebelled. It is thus with behaviorism that our story begins. Then we will turn to the cognitive revolution as a response to behaviorism, and only then will we be able to properly understand cognitivism in the study of animal minds. The tour finishes with two prominent challenges to cognitivism in the study of animal minds, the first being the historical challenge known as Morgan’s Canon and the second a contemporary update known as “the logical problem.” We will also look at some responses to these challenges.

## Behaviorism

In the early part of the twentieth century, the experimental methods of Wilhelm Wundt dominated psychology. For Wundt, experimental psychology meant the study of internal, conscious phenomena. These phenomena were available by a method of rigorously scientific self-observation or introspection. For the early behaviorists, the idea that an experimental science of psychology might be based on introspection was anathema. The behaviorists objected both to the introspective method and to the idea that psychology was the study of internal, conscious phenomena. Of course, these objections were connected. In

their attempt to make psychology a more scientific study, eliminating its reliance on introspective reports, behaviorists proposed to focus on the observable, namely, behavior. The goal of psychology, John Watson wrote in his 1913 Behaviorist Manifesto, is the “prediction and control of behavior,” and, as such, “introspection forms no essential part of its methods, nor is the scientific value of its data dependent upon the readiness with which they lend themselves to interpretation in terms of consciousness.” Watson went on to draw explicit connections between explanations of human behavior and explanations of animal behavior; he called for a science of psychology that treated human beings no differently than explanations of animal behavior treated animals. Just as we are unable to rely on an animal’s introspective testimony when we look for explanations of its behavior, so too should we not rely on a human being’s introspective testimony when we look for explanations of his or her behavior.

In fact, as we shall see, Watson’s move to think of animal behavior as similar to human behavior has multiple echoes in scientific attempts to understand and explain behavior. Watson was neither the first nor the last to argue that any differences between the explanations of human and animal behavior are differences in degree rather than in kind. Both Charles Darwin in the nineteenth century and Donald Griffin in the latter part of the twentieth century shared this perspective. Although, interestingly, as we shall also see, Watson’s challenge – that to treat animal and human behavior as having distinct causal origins is to fail to engage in rigorous scientific thought – has more in common with Darwin’s and Griffin’s detractors than with their supporters.

The idea that a psychological science can take as its subject matter intersubjectively unobservable data was rejected by the behaviorists. Instead, they advocated that psychology is best viewed as a science of behavior. Thus, behaviorism started with a rejection of introspection as an appropriate method for experimental psychology and with a rejection of internal conscious states as the appropriate subject matter of experimental psychology. The latter was replaced with behavior, external and intersubjectively

observable, and the former with the principle that any explanations of that behavior must themselves rely on intersubjectively observable events. Any useful or explanatory reference to mental or cognitive events can be translated into reference grounded in behavioral events. Any such reference that cannot be so translated is meaningless (Graham 2017; Greenwood 1999).

Instead of the sorts of internal states apparently found through introspection, behaviorists suggested that behavior be explained through histories of reinforcement and extinction patterns and by reference to environmental stimuli. To understand an individual’s history of reinforcement patterns related to a particular behavior is to understand why that individual persists with that behavior. Behaviorism is thus a kind of associationism. According to associationism – a theory of the mind historically attributed to David Hume (1738/1978) but often adopted in one guise or another by radical empiricists – ideas give rise to other ideas as a consequence of being associated with them, for example, because they co-occur. The same goes for behaviors. Associationism holds that when two events occur in proximity to one another, one tends to come to trigger the other. For the behaviorist an event becomes associated with a behavior, and thus the occurrence of that event comes to be the explanation for that behavior. For example, if a dog is given a treat each time it barks at a stranger, but not when it barks at an acquaintance, the pattern of rewards comes to explain why the dog barks at strangers, but not acquaintances. According to behaviorists, this sort of associationist explanation is not merely another tool in the box of possible explanations of human behavior; it is the primary, if not the only, tool in the box.

## The Cognitive Revolution

Even though behaviorism was a dominant research program in psychology (at least in the United States) from the second through the fifth decade of the twentieth century, two related factors spelled doom for this theoretical approach. The first was an alternative means of characterizing and explaining

human behavior: the emerging cognitivist approach. While both cognitivism and behaviorism postulated intervening variables in the explanation of behavior, behaviorism took these variables to be directly related to the exigencies of reinforcement, while cognitivism took these variables to be structured representations on which computations could be performed, which then yielded behavior. This proved to be a more powerful explanatory and research strategy. The other factor was a series of challenges to the orthodoxy of behaviorism. The most powerful and famous of these was Noam Chomsky's 1959 (reprinted in Chomsky 1967) review of B.F. Skinner's (1957) masterwork, *Verbal Behavior*.

By 1957, B. F. Skinner was the standard bearer for psychological behaviorism. *Verbal Behavior* was the culmination of 20 years of work (Palmer 2006). In it, he attempts to show how behaviorists can explain language use and comprehension. However, in a scathing review, Chomsky argued that the tools of behaviorism were inadequate to the task. Suppose a companion alerts Jones to the presence of a fox, by uttering the sound "fox." We might explain Jones's behavior (she looks for the fox, runs from the fox, or aims a rifle at the fox) by citing her past experiences of reinforcement related to the behavior she engaged in upon hearing the sound "fox." This explanation relies on there being previous instances of "fox" correlated with similar behaviors and with positive reinforcement. However, as Chomsky points out, the same behavior might occur without that history of hearing utterances of "fox" or of reinforcement. Chomsky's conclusion is that some other mechanism explains the behavior. There are similar problems with the behaviorist attempt to explain the production of language. Smith sees a companion step out into the street when a car is coming and yells, "watch out!" His companion jumps out of the way of the oncoming traffic. Are we to suppose that the explanation for Smith's yell is that the companion had previously reinforced that verbal behavior by jumping out of the way of oncoming traffic when Smith so yelled (and by failing to do so when he didn't yell)? Again, Chomsky concludes that the behaviorist explanation cannot be the complete explanation.

Chomsky's arguments were aimed specifically at the account of language put forward by Skinner in *Verbal Behavior*. One might take these objections to be limited to the domain of language, but as Chomsky noted several years later (1967), his unstated goal was to critique behaviorism more generally. It was in this spirit that his review was taken. His examples generalize nicely to other nonverbal behaviors. Consider Jones's response to utterances of "fox." Chomsky pointed out that Jones's behavior is predictable even without a history of reinforcement. More generally, if it is true that behavior is either random or explained by reinforcement, then novel behavior – behavior that, by definition (because it is novel), could not have been either reinforced or extinguished – should be random. In fact, much novel behavior is predictable. We would be surprised (to put it mildly) if Jones responded to "fox" by shaving her head, singing the national anthem of Greece, or begging for spare change. That is because we think that even though this may be Jones's first encounter with utterances of "fox," her behavior is caused by computations on structured internal representations that include a symbol related to "fox." Thus she might think, "In the presence of non-dangerous wild animals, look at the animal," and "A fox is a non-dangerous wild animal," and, consequently, she will look in the indicated direction.

This story – that with this one review Chomsky slew the Goliath that was behaviorism, what might be called the "origin myth" of cognitivism – is, of course, overly simplified. Even while behaviorism was the dominant research program in psychology, it was not the only research program; some psychologists continued to pursue studies of the human mind. In Europe, psychology never fell under the sway of the behaviorist hegemony. And some of the paradigm work of cognitivism predated Chomsky's review of *Verbal Behavior*. In his personal history of the cognitive revolution, Miller (1979) identifies a particular date as the birth date of cognitive science. This date, September 11, 1956, was prior to Chomsky's publication of his review of *Verbal Behavior*. (September 11, 1956, was the second day of an interdisciplinary conference at MIT.) Many of the

presenters at this conference are now recognized as the founding parents of cognitive science. One of these was indeed Noam Chomsky. Another was Miller himself, presenting his now famous research on “the magic number seven” on the limits and workings of memory (1956). Miller’s research was of foundational importance for cognitivism precisely because it showed that there was a structure governing internal processing. Similarly, the other work presented at the conference centered on the idea that the mind is an information processor (Bechtel et al. 1998). Moreover, while it is true that in the United States, behaviorism did wax and wane as the myth suggests, it has nevertheless remained a thriving discipline within psychology, even today, several decades after the cognitive revolution. Behaviorists today still reject Chomsky’s analysis of Skinner’s project (Palmer 2006).

In addition, the background against which this myth plays out, that behaviorism and cognitivism are competing and mutually exclusive paradigms and that the shift from one to the other is best described as a revolution are also misleading. Even those for whom cognitivist explanations in terms of operations on representations are the preferred mode of explanation of human behavior recognize that associationist explanations in terms of patterns of reinforcement are sometimes the correct explanations of human behavior. There is no inconsistency in holding that cognitive explanations are appropriate for some behavior and behaviorist explanations are appropriate for other behavior (Greenwood 1999).

Nonetheless, it is true that as a consequence of these developments, psychology took a turn toward cognitive explanations of human behavior. Rather than focusing on, say, patterns of reinforcement and extinction, these explanations focused on internal states including structured representations and the operations on these structured representations. It is worth emphasizing that the nature of the cognitive turn was not simply a rejection of the behaviorist doctrine that all behavior could be explained by patterns of reinforcement and extinction. Behaviorists were also willing to cite intervening, often internal,

variables. What made cognitivism stand out was the willingness to look to representations and other states as states that occurred between stimulus and response and the doctrine that those internal states were of explanatory import (Greenwood 1999). It is also worth noting in this context another factor that surely played a role in the move toward cognitivism: the rise of the computer age. A first approximation of the birth of the computer age could be taken to be the influential papers written by Alan Turing in the late 1940s, perhaps culminating in his (1950) *Computing Machinery and Intelligence* in which he proposes a general test for intelligence. The test is a behavioral test (if a human judge cannot discern a computer program from a human being, then the computer program is intelligent) and as such is firmly rooted in a behaviorist tradition that would describe intelligence as behaving in a particular manner. However, it wasn’t long before the computational metaphor, complete with its basis in operations performed on structured representations, began to influence the thinking of the new cognitivists. As Ulric Neisser (1988) observed, reflecting on those early days: “the computer had made a crucial contribution to psychology: It had given us a new definition of our subject matter, a new set of metaphors, and a new assurance.”

However, the cognitive turn was directed at explanations of human behavior alone. Watson’s (1913) call for treating human behavior as not explanatorily distinct from animal behavior was left behind in the move from behaviorist explanations to cognitive explanations of behavior. The implication was clear, if often unstated: we know that humans have internal representations (perhaps because introspection tells us this); however, we have no such evidence of the presence of internal representations in animals. (Chomsky was nearly explicit about this. He quotes Skinner’s claim that experimental work on animal behavior “can be extended to human behavior without serious modification” and spends much of his review arguing that such confidence is unsupported by both evidence and theory. As Palmer (2006) puts it, “Chomsky was betting that human verbal behavior is qualitatively different from the behavior of nonverbal

organisms; Skinner was betting that it isn't.") The division between animal and human behavior that Watson decried was once again alive and well in psychology.

## Cognitivism in the Study of Animal Minds

Watson wasn't alone in worrying about unscientifically supported attributions of psychological states. He was preceded in this by Conwy Lloyd Morgan. Morgan was not responding to the introspectionism of Wilhelm Wundt, as Watson did. Instead Morgan was motivated by what he saw as the weak anecdotal psychology of Charles Darwin and, more specifically, George Romanes. Darwin famously relied on anecdotes in his *Descent of Man* (1871) to conclude that there was a continuum of mental abilities between animals and humans. This is especially vivid in his discussion of emotions, where he writes of the anecdotes supporting the conclusion that animals engage in "long-delayed and artful revenge," of the happiness exhibited by "puppies, kittens, lambs, &c., when playing together." Even ants do not escape this anecdotalism: Romanes (1882) attributes no end of emotional fellow feeling to ants who act to remove impediments on other ants. They are, Romanes writes, "agitated," "perseverant," "fully informed," "sympathetic," and "excited" about the "rescue of" "their imprisoned comrade." Interestingly, in other moments, Romanes suggests that he'll adopt a much more cautious criterion for attributing mentality to nonhuman organisms: only consider those organisms able to make new adjustments in accordance with their individual experience, but instead of relying on this careful principle, he explicitly states that he is happy to rely on anecdotes, so long as they come either with the authority of "some name" or at least free from the possibility of "malobservation." It is not clear what he means by either of these criteria or why they should prevent the misattribution of mental states. Instead of following these criteria, Romanes seems to more closely adhere to a principle he cites, that if an inference from a particular behavior to particular mental

states is justified for one species, the same inference is justified for other species.

Morgan disagreed with both the anecdotalism and also, apparently, with Romanes's guiding principle. Rather than simply relying on comparative observations of behavior and deciding that if a piece of behavior is caused by mental states in the organisms of one species, then similar behavior is caused by mental states in the organisms of another species, Morgan offered his own canon in which he proposed that we be more careful in attributing psychological explanations.

In no case may we interpret an action as the outcome of the exercise of a higher psychical faculty, if it can be interpreted as the outcome of the exercise of one which stands lower in the psychological scale. (Morgan 1894, p. 53)

Perhaps the best example of an application of Morgan's Canon is also one of the most famous, namely, the case of "Clever Hans." Clever Hans was a horse who would apparently successfully add small numbers, counting out the solution with his front hoof and stopping when he reached the correct answer. However, it was discovered that Hans could only "add" correctly when accompanied by his trainer. The trainer would relax when Hans arrived at the solution. Apparently, Hans would detect the trainer's change in attitude and stop "counting." Thus we are presented with two competing hypotheses. According to the first, Hans was computing the answer to a simple problem in arithmetic. According to the second, Hans was merely responding to cues supplied by his trainer. Morgan's Canon dictates that we prefer the hypothesis that is the lowest "in the psychological scale." This is the second hypothesis, as it does not require us to believe that Hans was able to count, only to believe that Hans was sensitive to his trainer's cues. This is the conclusion that scientists at the time reached about Hans. (Notice that this may be different than the conclusion supported by Romanes's principle. According to that principle, if we would infer that a human being exhibiting similar behavior is genuinely counting, then we should infer that Hans is genuinely counting as well.)

Exactly the role that Morgan's Canon should play in evaluating phenomena such as exhibited in

the Clever Hans case is not clear. On the one hand, if Hans can only add when his trainer is present, then that suggests that he is not adding at all, but is responding to his trainer in some way. We can reach this conclusion without appealing to Morgan's Canon. On the other hand, maybe Hans is only interested in adding when his trainer is present. In such a case, Hans is able to add when his trainer is not present, but he simply does not want to. The presence of (and ease of devising) this alternative hypothesis suggests that some principle such as Morgan's Canon is needed to reach the conclusion that Hans is not adding, but is instead responding to cues from his trainer. We should continue to prefer the hypothesis that Hans is not computing sums because this hypothesis does not attribute to Hans the "higher psychical faculty" that is attributed to him by the other hypotheses. (There are other significant issues with Morgan's Canon. These are discussed below.)

It is worth noting that while Morgan's Canon seems to dictate that we explain Hans's behavior in some way other than by alluding to his ability to count, Morgan did not intend that the Canon rule out cognitive explanations of animal behavior. To the contrary, he firmly believed that some animal behavior was correctly explained in what we would now call cognitive terms. His goal was to ensure that such explanations were well founded, rather than based on vivid anecdote-based imagination. Despite this fact – that Morgan did not intend for his Canon to be used as an anti-cognitive cudgel – the combination of Morgan's Canon, behaviorism, and, more generally, the attitudes about animals expressed by Watson (1913) spelled doom for cognitive explanations of animal behavior (Greenwood 1999). Behaviorism teaches us that reference to cognitive states is unnecessary when it comes to explanations of human behavior. Morgan's Canon cautions us that we should always prefer lower explanations when such explanations are available. Since, according to behaviorism, there are always non-cognitive explanations available for human behavior, then it certainly seems to follow that there are always non-cognitive explanations available for animal behavior. Thus we should avoid cognitive explanations of animal behavior.

While Watson's attitudes about what counts as a reasonable explanation of animal behavior were explicitly directed at explanations of human behavior, they expressed a rejection of the idea that we would even consider explaining animal behavior in terms of mental states. Such explanations would, Watson implied, have to rely on introspective access to animal minds. Such access, unreliable in human beings, is completely absent in our investigations of and explanations of animal behavior. In tacitly endorsing this attitude toward animal minds, Watson was only the latest to rely on an argument that dated back at least to Descartes. Descartes (1637/1988) argued that language is the true, singular, mark of being minded. As animals are brutes (i.e., creatures incapable of language), they lack language, and thus they lack the ability to think. This argument, that language is required for thought, and thus that only creatures with language are capable of thought, is an appealing argument, as testified to by the fact that one can see it debated throughout the literature, even up to the present day (Allen 1992). Hume (1738/1978) supported the opposing hypothesis that the same explanations must be offered of the same phenomena whether found in humans or animals. As we have already seen, this hypothesis has a descendent in Romanes's thought, and it has echoes in contemporary scientific thinking about animal minds as well (Clatterbuck 2016).

Even when the yoke of behaviorism was lifted (as the myth goes), these prejudices about the proper explanations of animal behavior remained. So, even as founding ethologists such as Nikolaas Tinbergen and Konrad Lorenz carefully studied and reported on interesting behavior in various animals, they did not offer cognitive explanations of that behavior. It wasn't until Donald Griffin, already a well-established and respected scientist of animal behavior (elected to the American Academy of Arts and Sciences in 1952, founding Director of the Rockefeller Institute for Research in Animal Behavior in 1965), turned his attention to the study of animal awareness and consciousness in the middle 1970s (see, e.g., his 1976 publication) that the study of animal cognition became acceptable and cognitive ethology was born.

Griffin was well known as a hard scientist studying animal behavior (he was one of the scientists responsible for discovering that some bats use echolocation to navigate) when he published his book, *The Question of Animal Awareness*, in 1976. In this and in other works published at the time and in the following years, he argued that animals are conscious and that their minds should be the study of scientific investigation. This was truly the beginning of the cognitive revolution in the study of animal minds. It was only with Griffin's work that explanations of human behavior and explanations of animal behavior returned to the same realm: in both cases, cognitive explanations were now acceptable.

Of course, the history is not as straightforward as this suggests. For one thing, Griffin wasn't the first to discuss in print that animals were conscious. For example, Gordon Gallup (1970) suggested that the ability some chimpanzees apparently have to recognize themselves in mirrors suggest that they are agents with self-concepts, some of whose behavior may be best explained psychologically. Griffin may have been the most prominent researcher to endorse a positive attitude toward the possibility of animal consciousness and to encourage research in that direction. However, Griffin's suggestion that animals are conscious was met with significant hostility, even ridicule. Some scientists implied or even postulated outright that Griffin's suggestion was the consequence of an aging mind that was showing signs of dementia. Others took the suggestion seriously but argued that the evidence does not support cognitive explanations of animal behavior (see Bekoff and Allen 1997, for a catalog of different responses to the idea that animal behavior can be explained cognitively). Still, in some ways the debate about cognitive explanations of animal behavior was over before it gained any serious headway. Cognitive ethology quickly became a thriving area of scientific work. Fieldwork includes studies of communication (including alarm calls, warnings, informational calls, and differential responses to calls from different animals), learning, navigation, tool use, and cultural practices. By 1991, Carolyn Ristau, an expert in the behavior of piping plovers, reflecting

on the perspective afforded by the then well-established field of cognitive ethology, wrote that this shift in perspective led her to design experiments that she "had not otherwise thought to do, that no one else had done, and that revealed complexities in the behavior of the piping plover's distraction display not heretofore appreciated."

In addition to the growth in cognitively oriented fieldwork, there is a thriving practice of laboratory work, aimed at understanding how different animals understand the world. In addition to the areas just mentioned, this work includes studies focused on metacognition, language, and false belief tasks (Wimmer and Perner 1983). The literature on all of these is rich. A look at false belief tasks nicely reveals some of the debate in the field.

The false belief task is an experiment designed to show whether the subject recognizes that other individuals may have beliefs different from one's own. Anne may know that the cupcake is hidden in box 2, but Sally, who was out of the room when the cupcake was moved from box 1 to box 2, is unaware of this fact. Can Anne attribute to Sally the false belief that the cupcake is in box 1? If so, then Anne is able to draw a distinction between the belief she has (that the cupcake is in box 2) and the belief that Sally has (that the cupcake is in box 1). Doing so requires that Anne attribute to Sally beliefs different than her own. That is, if Anne is successful, she apparently thinks of other people as having minds. Anne is, in the parlance of the field, a mind-reader.

Versions of the Sally-Anne task, of false belief tasks, have been attempted with various animals (e.g., Hare et al. 2001). For example, in an ingenious series of experiments (one which has sparked many variations in animal experiment facilities around the world), Brian Hare et al. (2001) devised an experimental setup in which a subdominant chimpanzee is competing with a dominant chimpanzee for food. Generally, the subdominant will cede to the dominant in direct competition, but in this task, the more desirable food is hidden behind an occluding screen so that the subdominant can see it, but his dominant competitor cannot. If the subdominant attempts to retrieve the desirable food, then his behavior is an indication that he believes the dominant

chimpanzee is unaware that the desirable food is present. Like Anne in the false belief task, the subdominant chimpanzee seems to be attributing to the dominant chimpanzee, a belief that is different than his own. While the results of these and other related experiments are open to debate, the fact of the application of the task to nonhuman animals is a clear indication that Griffin's arguments have held sway: scientists are actively investigating the nature and extent of animal minds.

## Challenges to Cognitivism in the Study of Animal Minds

### Morgan's Canon

Or maybe the dominance of the cognitivist approach is not so clear. There is another way of looking at these issues. One way is, as suggested above, to notice that whatever the theoretical debate might be, Griffin's (1976) book has had a dramatic effect on the scientific study of animal behavior. But it has been 40 years and the debate has shown no signs of abating. From this other perspective, the criticisms of Griffin's book and of the cognitivist approach to understanding animal behavior are a reminder of the importance of adhering to Morgan's Canon. Those scientists who rejected Griffin's arguments were, once again, stressing the lessons learned from Morgan nearly a century earlier. Remember that, colloquially speaking, Morgan urged that we never attribute a higher-order psychological property when the behavior in question could be explained with a lower-order property. A natural way to interpret Morgan's Canon is as a proscription against loosely attributing psychological states to animals simply on the basis of anthropomorphism (as did Romanes and Darwin). Instead we ought to do so only on when the evidence demands such attributions. On this reading, Griffin's critics are objecting that when Griffin argues that animals are conscious, he is violating Morgan's Canon by opting for explanations that attribute to animals more advanced psychological states than the evidence actually demands. According to this picture, the field is divided between those who

would loosely attribute cognitive states to animals and those who are more careful to attribute those cognitive states only when no other explanation of their behavior is available.

The situation is not as straightforward as this description suggests, however. Start with the fact that any behavior taken on its own can be explained non-psychologically. For example, as discussed above, verbal behavior is taken to be the paradigm of an expression of internal psychological states. But some behavior that looks a lot like verbal behavior – the behavior of parrots, both human and avian – does not warrant a psychological explanation. This suggests that it is never the case that the only available explanations of a piece of behavior are psychological. But, on the other hand, even Morgan himself thought that some animal behavior warrants a psychological explanation. This presents a conundrum: if no behavior demands a psychological explanation, but Morgan thought that some behavior is best explained in psychological terms, then Morgan's understanding of his own Canon must have been different than the contemporary understanding (according to which Griffin is going too far by loosely attributing cognitive states to animals when the evidence did not force him to do so).

If we are to rely on Morgan's Canon as a principle guiding scientific inference, we ought to take a closer look at exactly what it asks of us and why. Which psychological properties are higher and which are lower? What is the basis for this implicit scale of psychological properties? And, perhaps most important, why should we avoid attributing higher-order properties when we could explain behavior by appealing to lower-order psychological properties? The most common interpretations of Morgan's Canon are that it is an appeal to parsimony or to simplicity. Perhaps Morgan is urging us to avoid attributing psychological states to animals when we don't need to. Or perhaps he is urging us to avoid overly complex explanations. Both of these seem like good goals.

Most endorsements of Morgan's Canon cite it as an application of parsimony (e.g., Vauclair 1996). We should prefer those explanations that avoid needlessly postulating entities that are

not required to account for the evidence. But one needs to be careful when wielding the shears of parsimony. Postulating that Hans is able to count only adds entities to our ontological ledger sheet when in doing so we are attributing to Hans abilities that we don't think he already has and when the alternative explanation does not involve attributing to Hans abilities that we don't think he already has. That an explanation cites cognitive states does not on its own make the explanation non-parsimonious. Consider an explanation of your friend's smile when she sees you. Perhaps she's happy to see you. Or, perhaps her smile is a conditioned response to your smile, and she has no emotions whatsoever. We don't reject the first explanation on the basis of parsimony; even though it relies on cognitive states absent from the second explanation, it does not rely on cognitive states that we do not already think to be present in your friend. Sometimes the parsimonious explanation is the one that cites cognitive states. If we know that Hans wants to please his trainer, then we might prefer to explain his behavior by talking about that desire to please (a desire which attributes to Hans the second-order state of thinking about his trainer's state of mind) rather than by talking about his ability to count. Because Morgan's Canon suggests that we prefer the non-cognitive explanation, but parsimony sometimes favors the cognitive explanation, Morgan's Canon is not an application of parsimony.

Another common interpretation of Morgan's Canon is that it is an appeal to the desideratum that explanations be simple (e.g., Shettleworth 2012). Unlike appeals to parsimony, which are grounded in the idea that the explanation that accounts for the data while postulating the fewest additional elements to our ontology is the explanation most likely to be correct, appeals to simplicity are grounded in the idea that the explanation most likely to be correct is the simplest. But when it comes to explanations of animal behavior, why should we think that explanations that appeal to psychological properties are simpler than explanations that do not appeal to psychological properties? Certainly some psychological explanations are more simple than some nonpsychological explanations. For example, suppose we were to be deciding

between the following explanations of Hans's behavior: the cognitive explanation that attributes to Hans the ability to count and the non-cognitive explanation that relies on a science fiction fantasy in which a nefarious neurosurgeon is controlling Hans's behavior by means of a remotely activated receiver placed in Hans's brain. In this case, the cognitive explanation seems simpler. Simplicity on its own does not recommend non-cognitive explanations over cognitive explanations. At the very least, we need grounds to think that non-cognitive explanations are somehow simpler than cognitive explanations.

The defender of Morgan's Canon might respond that Morgan himself has provided such grounds. Morgan justified his Canon with appeals to evolution by natural selection. Thus the idea is that we can categorize explanations as higher or lower with the support of evolution. We can think of this as an intuitive appeal to the idea that as evolution proceeds, organisms grow more complex and able to pursue more complex goals by more complex means. Human beings have complex representations, some of our closest relatives may have simpler representations, and animals distantly related to us have even simpler representations or no representations at all. But, as detailed in many recent attacks on Morgan's Canon in the philosophical literature (e.g., Fitzpatrick 2008), this picture is not supported at all by the current thinking about evolution. First, this way of thinking about evolution places human beings at the pinnacle of evolutionary progress, but neither is evolution a progression nor is there any pinnacle toward which evolution might progress. Nor are human beings any more advanced than any other species; each species is evolutionarily fit for its own niche. It follows from this that there is no support from evolution for a naturalistic idea of a psychological scale on which "higher" and "lower" might be placed. Second, the idea that evolution moves from simplicity to complexity is undermined by the evidence. Evolution within a species can be described as fitting a general trend according to which members of the species move from being less fit for a particular niche to more fit for that niche. This evolutionary change sometimes involves moving from a less complex

trait to a more complex trait and sometimes involves moving from a more complex trait to a less complex trait. Finally, there is no reason to think that more complexity is less simple, that organisms with complex representational abilities developed those abilities out of simpler representational abilities.

On the whole, due to arguments such as these, Morgan's Canon is out of philosophical fashion at the moment. If a challenge to the application of the cognitivist perspective to the study of animal minds relies on Morgan's Canon, then that challenge seems unlikely to succeed. However, there is another similar argument that has proved to be important in contemporary debates about animal minds: The Logical Problem.

### The Logical Problem

Unlike Morgan's Canon, which relies on an unstated principle about the nature of scientific reasoning and which seems to depend on a misunderstanding of the nature of evolution by natural selection, the logical problem makes an explicit appeal to simplicity/parsimony and makes no assumptions about the nature of evolution. The argument, originally made by Povinelli and Vonk (2003), targets the mind-reading literature, but, as we will see, it can be easily extended to experimental results in other domains.

Remember that mind-readers are individuals some of whose behavior is predicated on an inference about what another individual is thinking. Povinelli and Vonk point out that mind-reading is a two-stage process. The mind-reader must first observe the behavior of the individual whose mind is being read and then infer that the behavior signifies a particular mental state. That is, every individual who is a mind-reader is also a behavior-reader. But it follows from this that to attribute to an individual the ability to mind-read is to attribute to that individual the ability to do two things: read minds and read behavior. Thus, the logical problem is: if we can explain an individual's behavior by postulating that she is a behavior-reader, why postulate that there is also something else that she can do? Because there is no need to postulate that she is a mind-reader, any theory that makes that claim is going beyond what the evidence demands.

Notice that while Povinelli and Vonk's argument is directed at postulations of mind-reading ability, it can be easily generalized to bear on any similarly cognitive explanation of animal behavior. The cognitivist claims that between stimulus and response there is an additional step involving the manipulation of representations. In the mind-reading case, the cognitivist claims that the subject animal forms a representation of another animal's mental state, but Povinelli and Vonk object that there's no reason to suppose that the subject's behavior is mediated by a representation of the other's mind when it might be caused simply by a representation of the other's behavior. But why stop there? In a case involving learned or habitual behavior, we might ask a similar question: why suppose that the behavior is caused by a representation of the state of affairs the animal is responding to when the state of affairs might simply trigger the behavior via an associationist mechanism? (This was the behaviorist insight.) But why stop even there? When an animal does something apparently truly novel – e.g., a crow bends a stick to use as a tool to fetch food – isn't that novel behavior composed of behaviors that were rewarded individually? If we have to postulate the existence of those prior rewarded behaviors in order to explain the current novel behavior, then Povinelli and Vonk's argument supports the objection that we are postulating two intervening steps – the prior rewarded behaviors and a structured representation – when only one such step is needed. Once we have made this observation, we can see that Povinelli and Vonk, while they are avoiding the kinds of claims that bedevil Morgan – claims about higher and lower and about evolution of mental traits – are in fact providing an update of Morgan's Canon. As their argument seems to generalize to all cognitive explanations, and it favors explanations that are non-cognitive, purely on the basis that the cognitive explanations are, from a logical standpoint, needlessly complex, they are providing a sound basis for rejecting cognitivism in favor of explanations that do not cite cognitive states. And, like Morgan, they may not view themselves as giving an argument against cognitive explanations of animal behavior. Instead, they are providing a criterion for those

explanations: when we appeal to cognitive states in our explanations of animal behavior, we must not do so when our explanations include non-cognitive states which could explain the behavior just as well. The logical problem is that the cognitive explanations cite both cognitive and non-cognitive states in the explanation of some behavior when only one (the non-cognitive) is required for explaining the behavior in question.

The logical problem arises whenever we attempt to explain an instance of animal behavior; for every cognitive explanation of an instance of animal behavior, there is always a simpler non-cognitive explanation that cites fewer states. The central response to this challenge has been to accept that the logical problem arises whenever we attempt to explain an instance of animal behavior but to point out that the logical basis of the challenge shifts when we shift our attention from one instance of animal behavior to many instances. For example, Call and Tomasello (2008) argue that while it may be simpler to think that an animal is reading behavior when it acts as if a conspecific is threatening (rather than reading the behavior and inferring that the conspecific is occupying a particular mental state), but when it comes to all of the different behaviors an animal may have to read – threats, food-sharing behaviors, food-hoarding behaviors, mating behaviors, mating-avoidance behaviors, etc. – it can turn out to be simpler to postulate that the animal is engaged in mind-reading. That is, one mind-reading faculty can be useful in responding to a great variety of behaviors, while the animal without the mind-reading faculty would need a behavior-reading faculty for each of the different behaviors. Similarly, Saidel (2018) argues that Povinelli and Vonk make a mistake similar to one that Morgan makes: treating an animal's behavior in isolation from its other behaviors and from what else we know about the animal may enable us to explain the behavior more simply than we otherwise would, but it also forces us to miss the full picture. It is the full picture that ought to move us to accept or reject a cognitive explanation of the animal's behavior. These are by no means the only responses to the logical problem. These responses make it clear that Povinelli

and Vonk have stirred a healthy debate and that their objections have done nothing to slow the study of animal cognition nor the appeal to cognitive states in order to explain animal behavior.

There are other challenges to cognitivism, both in the study of animal minds and in human psychology. Some researchers who have grown out of the cognitivist tradition (and who consequently reject behaviorism) object to the idea that behavior is best explained by appealing to structured representations. According to many of these thinkers, the traditional computer metaphor for the mind has led our theories astray. Others think that the cognitivist approach is too focused on the mind that even while it pursues the scientific study of the mind, it does so from a perspective that owes too great a debt to dualistic intuitions about the relationship between the mind and the body. Instead, they propose that if we think about the mind as essential part of the body, we will come to a different and better understanding of the mind. In spirit, though, these challenges are products of the successes that cognitivism has brought, in the studies of both human and animal minds, and as such, they are testimony to the power and success of the cognitive revolution.

## Colonial Nesting

Charles R. Brown

Department of Biological Sciences, University of  
Tulsa, Tulsa, OK, USA

Many animals breed at spatially restricted sites in relatively close proximity to others of the same or a different species. Colonial nesting is especially widespread in birds, insects, and spiders and can often involve unrelated individuals breeding in high density. Some bird colonies consist of up to 200,000 nests, while spider colonies can reach >50,000 individuals (Brown 2016). Colonial nesting confers three major benefits to individuals (Alexander 1974): (1) predators may be better avoided by increased vigilance, active defense, or a statistical reduction in the per capita likelihood of being a victim; (2) food-finding can be enhanced by observing where other colony members forage, cooperatively hunting, or (in rarer instances) active signaling as to the whereabouts of food; and (3) nesting sites that are safe from predators or provide otherwise appropriate nesting substrate are limited within the landscape. Colonial nesting in most species is thought to have evolved in response to one or more of these benefits, although there is still debate as to the relative importance of each (Danchin and Wagner 1997; Brown and Brown 2001).

Individuals nesting in colonies also experience costs associated with high-density breeding. Two universal ones are an increased likelihood of

contracting parasites or disease from other group members and increased competition for resources such as food, nesting sites, or mates (Alexander 1974). Other costs that apply in some species include a colony's increased conspicuousness to predators and a greater likelihood of misdirecting parental care to unrelated offspring (via extra-pair fertilizations or parasitic egg laying in nearby nests) (Brown and Brown 2001). These costs are thought to be severe enough to prevent colonial nesting in many species and are presumably overcome to various degrees by the advantages of grouping in species that are colonial.

Habitat selection appears to drive colonial nesting in some animals (Danchin and Wagner 1997; Safran et al. 2007). When settlers are naïve about the quality of breeding habitat, they may be attracted simply by the presence of other animals at a site, and in these cases colonies form as different individuals respond in the same way to the same social cues. In other cases, animals assess the reproductive success of residents at a given site and, when success is predictable between years, may use that information to select that same site the next season.

Most species that live in colonies exhibit substantial variation in colony size, with size often varying by several orders of magnitude within the same population (Brown 2016). Colony size variation may be genetically based at least in part, with individuals preferring colonies similar in size to where they were born (Brown and Brown 2000) and reflecting individuals' sorting among colonies (based on life-history traits, morphology, or behavioral propensities) to find the social environment to which they are best suited. Colony size variation is maintained in some species by fluctuating directional or stabilizing selection that alternately favors individuals in different group sizes and causes a range in colony sizes to persist over the long term (Brown et al. 2016). In other species, the costs of dispersal, reliance on imperfect information about site suitability, and collective nonrandom movement by individuals can also lead to colony size variation (Brown 2016).

Colonies often consist of collections of individuals with different behavioral tendencies or "personalities." For example, individuals

sometimes forage most successfully if their colony contains both aggressive and nonaggressive phenotypes (Keiser and Pruitt 2014). The relative proportion of different personality types may affect group dynamics and ultimately individual fitness (Bergmüller and Taborsky 2010; Pruitt et al. 2013) and thus may be important in the evolution of colonial nesting more generally.

## Color Change

Lindsey Swierk

School of Forestry and Environmental Studies,  
Yale University, New Haven, CT, USA

Color change in animals is a taxonomically widespread type of phenotypic plasticity, in which the body coloration of an individual is altered over the course of seconds, minutes, days, seasons, or a lifetime. This within-individual change can be induced by external (e.g., social interactions) or intrinsic factors (e.g., circadian rhythms), may or may not be adaptive, and may or may not be reversible. Color change can refer to a change in the spectral reflectance of the entirety of an individual's body, only a small portion of the body surface, or anything in between, including changes in patterns or mottling of all or part of the body surface. Adaptive color change can serve a variety of functions, such as thermoregulation, communication, and camouflage. Mechanisms of color change are nearly as diverse as the types of color change themselves, illustrating a diversity of evolutionary strategies converging to achieve similar goals. Color change can influence the persistence of animal populations in an increasingly anthropogenically altered world by differentially affecting key life functions, including predator avoidance, thermoregulation, and mate attraction, in human-altered habitats.

## Types of Color Change

Animal color change can be broadly grouped into two categories: morphological and physiological. Both morphological and physiological color

change rely on a diversity of pigment cells (chromatophores), particularly in ectotherms. Chromatophores include melanophores (brown or black pigment), xanthophores (yellow), erythrophores (red/orange), and iridophores (iridescent), among others. Blue and some green colors in animals are typically produced structurally (e.g., via diffraction gratings or crystal fibers). Some animal colors are produced by a combination of pigments and structural colors.

Morphological (chromogenic) color changes are driven by the creation or degradation of pigments and the number or type of chromatophores, which effectively alter pigment concentration in the skin. Morphological color change can be reversible or irreversible. Long-term cyclic changes, such as seasonal increases in melanin that permit improved solar heat absorption in snakes during colder months, are common examples of morphological color change. Most ontogenetic color changes, which occur as individuals age, are also examples of morphological color change, though these tend to be irreversible changes associated with accruing sexual coloration or altering coloration to maximize camouflage from juvenile to adult habitats.

Physiological (chromomotor) color changes occur much more rapidly, in seconds to minutes, and are typically driven by the dispersal and reaggregation of pigments in chromatophores or by rapid changes in the orientation and consequently the light reflectance of crystalline plates. Mechanisms of physiological color changes have been well studied in lizards. The rapid dispersal of melanin following stressful social encounters in many *Anolis* lizards produces a color change from green to brown within seconds (Greenberg 2002). The structural colors of *Urosaurus* lizards likewise change rapidly: reducing the spacing between adjacent iridosomes decreases long-wavelength radiation scattering, which increases “blueness” of abdominal tissue with temperature (Morrison et al. 1996).

A third class of animal color change could be considered behavioral, as it relies on the choice of an individual to utilize substances to alter its coloration. Greater flamingos, for instance, produce carotenoid-rich oily secretions that are actively

spread over their plumage as “makeup” during mating seasons (Amat et al. 2011), and bearded vultures stain their plumage with iron oxide from soil, likely to advertise dominance (Negro et al. 1999). Though mechanistically distinct, these behaviorally driven color changes appear to serve similar roles in species’ ecologies as do morphological and physiological color changes.

## Functions of Color Change

Color change can provide a wide variety of adaptive functions. Though not all color change is adaptive (e.g., color change induced by pathogen or parasite infection), color change can serve innumerable beneficial roles related to survival and reproduction across animal taxa. Change in color, brightness, and pattern of an animal’s body surface is widely used for predator avoidance. The circadian rhythm-driven color change of horned ghost crabs evolved to optimize background matching in both day and night lighting conditions. Many cephalopods rapidly alter their coloration and pattern to provide maximum concealment via either background matching or disruptive coloration to mask their body outline, depending on the substrate. Predation pressure is not the only force selecting for camouflage-related color change; crab spiders utilize color change to conceal themselves within inflorescences of variable colors to deceive their prey (Anderson and Dodson 2015). In lieu of camouflage, some species use color change to deceive predators or prey via mimicry: for example, the dusky dottyback (*Pseudochromis fuscus*) can alter its coloration to mimic that of surrounding schooling fish and thereby increase prey capture success while simultaneously reducing detection by its own predators (Cortesi et al. 2015).

A variety of species exhibit body coloration changes over maturation. Juveniles of some lizard species bear bright tails to direct predator attacks to a more expendable body region, whereas adults lose bright tail coloration as their activity patterns and habitat use (and concomitant selective pressures) change with maturity. Ontogenetic color change can also be used as a strategy to avoid

mating harassment. Some female damselflies (*Ischnura senegalensis*) use immature-specific coloration to deter costly male attention, wearing “mature” colors only at sexual maturation (Takahashi et al. 2012).

Short-term alterations in social state are often conveyed by reversible changes in color. Chameleons, a lizard group popularly recognized for their color-changing abilities, rapidly darken their skin to communicate subordination in male-male contests or heighten conspicuous coloration during courtship and male combat (Stuart-Fox and Moussalli 2008). Male cichlids (*Astatotilapia burtoni*) alternate among blue, yellow, and cryptic color morphs depending on hormone concentrations associated with success in agonistic encounters (Korzan et al. 2008). Other social functions of color change include, but are not limited to, seasonal mate advertisement, mating or parental status, and honest indicators of quality or parental ability. Due to the speed and reversibility of physiological color change, many of these messages are conveyed to conspecifics in real time.

Color change is also widely used to protect individuals from abiotic pressures. One important abiotic selective pressure driving color change is solar irradiation. Many species evolved color change as a protective mechanism against excessive heat absorption (in which colors tend to lighten to maximize reflectance) and to permit more rapid warming in cooler temperatures (in which colors tend to darken). For example, some *Uca* fiddler crabs adjust carapace brightness depending on temperature as a thermoregulatory mechanism. Photoprotection is another abiotic driver of color change. Some species, such as the Kerry spotted slug (*Geomalacus maculosus*), increase melanization in response to ultraviolet light exposure to reduce the risks associated with ultraviolet radiation (O’Hanlon et al. 2017).

Color-changing species may experience conflicting color optima, particularly in species in which coloration is used both for crypsis and communication. In the western rainbow fish (*Melanotaenia australis*), subordinate males that darken their body coloration for substrate matching subsequently experience greater attacks from dominant male conspecifics, as increased

melanization is also used to communicate dominance in this species (Kelley et al. 2016).

Despite its advantages, the ability to change color can also be physiologically costly. Pigments are either derived from the environment (e.g., carotenoid pigments obtained from food) or synthesized directly (e.g., melanin), either method involving energy expenditure. For example, guppies induced to change color require greater food intake compared to those not induced to change color (Rodgers et al. 2013). In addition, some pigments required for color change are also used for other vital functions, namely immunity, exacting a potentially costly trade-off.

## Animal Coloration and Global Change

How global change interacts with animal color change will increasingly become a focus for investigation. Though color change can provide individuals with the ability to respond to natural abiotic and social changes in their habitats, if and the extent to which color change enables species to cope with anthropogenic stressors is unclear. New evidence suggests that some color-changing species may fare particularly poorly due to mismatch with current climate patterns. The white-brown springtime fur transition of snowshoe hares (Zimova et al. 2016) is now asynchronous with the current timing of the seasonal melting of snowpacks and has demonstrable fitness costs; these observations are likely repeatable in species that similarly evolved seasonal snow-related camouflage. With increasing average global temperatures, species that use color change for thermoregulation may likewise experience costs. Body color lightening in lizards for thermoregulatory purposes can conflict with body color darkening for camouflage, leading to a sub-optimal balance between thermoregulation and predator avoidance as habitats warm globally. When body color lightening is a sexually selected trait used primarily during courtship, as it is in *Uca* male fiddler crabs that temporarily lighten their carapaces during mating displays, natural selection for lighter carapaces for thermoregulatory benefits in a warming world could reduce the

strength of sexual selection for lighter carapaces, with unknown population-level consequences. Anthropogenic stress can also strongly affect color-changing sexual signals, as illustrated by the duller sexual colors of European tree frogs following exposure to traffic noise (Troianowski et al. 2017).

## Common Ancestor

Rohini Motwani

Department of Anatomy, ESIC Medical College,  
Hyderabad, India

### Definition

“Common ancestor” is defined as an ancestor shared by two or more descendant lineages, or we can describe in other way as an ancestor that they have in common.

### Introduction

“**Evolution by natural selection,**” which is one of the best theories of Darwin, is supported by evidences from a wide variety of scientific disciplines, including paleontology, geology, genetics, and developmental biology (Darwin 1859). This theory says that all the species are related to one another like sisters, cousins, and distant kin in a vast family tree of life. Another strong idea given as Darwin’s postulates was under development: the “cell theory.” According to this new theory, the cells were the most basic units of life. From these two powerful theories of Darwin, there emerged the idea of a single organism that should represent the universal ancestor of all living beings. We can say that all life on Earth has arrived from one common ancestor whose descendants underwent divergent selection; thus we would find common ancestors between ourselves and every other living organism (Pontzer 2012). But exact origin of modern human being is still a topic of debate. Thus the existence of a common ancestor to all living organisms in Earth is an outcome of Darwin’s idea of common ancestry.

### Miocene Epoch

Who is our “real ancestor”? This question would always be a topic of debate. To understand this

we need to understand the process of evolution and from what sort of animal we have evolved from!

**Miocene Epoch**, which is the major division of the Neogene Period (23 million years to 2.6 million years ago) that extended from 23 million to 5.3 million years ago. It is often divided into the Early Miocene Epoch (23 million to 16 million years ago), the Middle Miocene Epoch (16 million to 11.6 million years ago), and the Late Miocene Epoch (11.6 million to 5.3 million years ago) (The Editors of Encyclopaedia Britannica 2018).

In the Early Miocene Epoch, fossil apes were associated mainly with forest environments, and they were pronograde arboreal slow climbers and with some indications of terrestrial behavior, particularly the larger species. Thumbs in their hands were long and opposable, and the phalanges were curved. In the early Middle Miocene Epoch, the apes were still monkey-like in their body posture and were associated almost entirely with non-forest, deciduous woodland habitats, with increasing evidence of terrestrial adaptations. Hand proportions remained the same. Toward the end of the Middle Miocene (12 mya), some fossil ape species had broadened chests, long clavicles, medial torsion of the humerus, and repositioning of the scapula to the back (Andrews 2019). These adaptations may have been linked with more upright posture, as in the living apes, but unlike them, the hand phalanges were short, robust, and less curved, and the thumb remained long. Associated environments were deciduous woodland rather than forest. This body plan was retained in part in some later Miocene apes (10 Ma); some of which also had more elongated limbs and hands (thumb length not known) and hind limbs modified for greater flexibility. Other Late Miocene European apes had adaptations for living on the ground, and some of these also shared characters of the skull with orangutans. They were associated with more open deciduous woodland habitats. This body plan and environment were retained in the early hominin, *Ardipithecus ramidus*, but with a more robust postcranial skeleton and incipient bipedalism.

## Early Hominins

**Hominin**, any member of the zoological “tribe” Hominini (family Hominidae, order Primates), of which only one species exists today – *Homo sapiens* or human beings. The term is used most often to refer to extinct members of the human lineage, some of which are now quite well-known from fossil remains: *Homo neanderthalensis* (the Neanderthals), *Homo erectus*, *Homo habilis*, and various species of *Australopithecus*. Our immediate evolutionary family is comprised of the **hominoids**, the group of **primates** that includes the “lesser apes” (siamangs and gibbons) as well as the “great apes” (chimpanzees, bonobos, gorillas, and orangutans). Among the great apes, our closest relatives are the chimpanzees and bonobos. The fossil record, along with studies of human and ape DNA, indicates that humans shared a common ancestor with chimpanzees and bonobos sometime around six million years ago (mya).

The human-chimpanzee last common ancestor (HC-LCA) is the species from which the **hominin** lineage and the chimpanzee and bonobo lineage diverged. Hominins are species on our branch of the hominoid tree after the split with the chimpanzee and bonobo line, including all of the extinct species and evolutionary side branches.

Although the evolution of hominid features is sometimes put in the framework of “apes vs. humans,” the fact is that humans are apes, just as they are primates and mammals. The other apes – chimpanzee, bonobo, gorilla, orangutan, and gibbon – would not form a natural, monophyletic group (i.e., a group that includes all the descendants of a common ancestor), if humans were excluded. Humans share many traits with other apes, and those other “apes” (i.e., non-human apes) don’t have unique features that set them apart from humans. Humans have some features that are uniquely our own, but so do gorillas, chimpanzee, and the rest. Hominid evolution should not be read as a march to humanness (even if it often appears that way from narratives of human evolution). Students should be aware that there is not a dichotomy between humans and apes. Humans are a kind of ape.

Much discussion in human paleontology surrounds the evolution of a bipedal, upright stance. When and why did this occur? One thing to keep in mind is that “bipedal” and “upright” are not equivalent terms. An animal can be bipedal without having a vertical backbone. It seems clear from the fossil record of hominids that habitual bipedality preceded the evolution of a recurved spine and upright stance. Other changes in the gait, such as how the relatively “splayed” gait of chimps evolved into the gait of humans, who put one foot directly in front of the other, involve studying the hip joint, the femur, and the foot.

### Australopithecus Afarensis

This species is one of the best known of our ancestors due to a number of major discoveries including a set of fossil footprints and a fairly complete fossil skeleton of a female nicknamed “Lucy” (Johanson and McHenry 2018). These are the earliest members of the genus *Australopithecus*, hominins which were adept terrestrial bipeds but continued to use the trees for food and protection. *Australopithecus afarensis* is usually considered to be a direct ancestor of humans. This species lived between 3.9 and 2.8 million years ago. *Australopithecus* means “southern ape” and was originally developed for a species found in South Africa 1924 (Dart 1925). This is the genus or group name, and several closely related species now share this name. The word afarensis is based on the location where some of the first fossils for this species were discovered. We now know that *Australopithecus* was a highly successful genus that persisted for nearly three million years.

### The Genus *Homo*

The earliest fossils of our own genus, *Homo*, are found in East Africa and dated to 2.3 mya (Kimbel et al. 1997). These early specimens were similar in brain and body size to *Australopithecus* but show differences in their molar teeth, suggesting a change in diet. In general, *Homo* differs from *Australopithecus* in its trend

toward ecological behavior, encephalization, and flexibility in nature. Another distinction between the two – where *Homo* is defined on the basis of enlarged absolute brain size ( $>600\text{ cm}^3$ ) and “complex” behavior, including tool use and language – long formed the bedrock of investigation into the origins of *Homo*. Wood and Collard (1999) defined *Homo* as a “monophylum [the common ancestor and all the descendants] whose members occupy a single adaptive zone.”

***H. habilis*** (2.3–1.4 mya), the oldest member of the genus *Homo*, was found in East Africa and was associated with simple stone tools and butchered animal bones (Blumenshine et al. 2003). ***H. erectus*** was found throughout Africa and Eurasia and persisted from 1.9 mya to 100 kya, and perhaps even later (Anton 2003). Like modern humans, *H. erectus* lacked the forelimb adaptations for climbing seen in *Australopithecus*. Its global expansion suggests *H. erectus* was ecologically flexible, with the cognitive capacity to adapt and thrive in vastly different environments. Not surprisingly, it is with *H. erectus* that we begin to see a major increase in brain size, up to 1,250 cc for later Asian specimens.

*H. erectus*, around 700 kya, earlier in Africa gave rise to ***H. heidelbergensis***, a species very much like us in terms of body proportions, dental adaptations, and cognitive ability (Rightmire 2009). *H. heidelbergensis*, often referred to as an “archaic” *Homo sapiens*, was an active big-game hunter, produced sophisticated Levallois style tools, and, by at least 400 kya, had learned to control fire (Roebroeks and Villa 2011).

According to one theory, Neanderthals, Denisovans, and modern humans are all descended from the ancient human *Homo heidelbergensis*. Between 300,000 to 400,000 years ago, an ancestral group of *H. heidelbergensis* left Africa and then split shortly after (Rightmire 2008; Hublin 2009). One branch ventured northwestward into West Asia and Europe and became the Neanderthals. The other branch moved east, becoming Denisovans. By comparing the genomes of apes, Denisovans, Neanderthals, and modern humans, scientists hope to identify DNA segments

unique to the different groups. Early results already suggest modern humans underwent genetic changes involved with brain function and nervous system development, including ones involved in language development, after splitting from Neanderthals and Denisovans. Identifying and understanding these genetic tweaks could help explain why our species survived and thrived while our close relatives died out.

### **Homo Neanderthalensis (*Homo sapiens* Neanderthalensis)**

The name Neanderthal (or Neandertal) derives from the Neander Valley (German Neander Thal or Neander Tal) in Germany, where the fossils were first found. They are member of a group of archaic humans who emerged at least 200,000 years ago during the Pleistocene Epoch (about 2.6 million to 11,700 years ago) and were replaced by early modern human populations (*Homo sapiens*) between 35,000 and perhaps 24,000 years ago. They inhabited Eurasia from the Atlantic regions of Europe eastward to Central Asia. Until the late twentieth century, Neanderthals were regarded as genetically, morphologically, and behaviorally distinct from living humans. However, more recent discoveries about this well-preserved fossil Eurasian population have revealed an overlap between living and archaic humans (Tuttle et al. 2020).

### **Denisovans**

The Denisovans are a much more recent addition to the human family tree. In 2008, paleo-anthropologists digging in a cave in Southern Siberia unearthed a 40,000-year-old adult tooth and an exquisitely preserved fossilized pinkie bone that had belonged to a young girl who was between 5 and 7 years old when she died. Recently, scientists successfully extracted nuclear DNA from the pinkie bone and conducted comparison studies with the genomes of modern humans and Neanderthals. Studies show the girl was closely related to Neanderthals yet distinct enough to merit

classification as a new species of archaic humans, which scientists named “Denisovan” after the cave where the pinkie bone was found. Genetic studies revealed that the Neanderthals and the “Denisovans” are more closely related to each other than either group is to modern humans (Tuttle et al. 2020).

## “Ghost” Hominids

Genetic study of *Homo sapiens* DNA pool has helped many researchers to shed light on where our ancestors made contact with other human subspecies. But in a new analysis of populations from West Africa, they have started to kick up something unexpected: hidden inside genomes are signs of as-yet-unidentified genetically distinct human ancestors that we never knew existed. Geneticists call them “ghosts” population (Brahic 2018). There are no physical record of these ancient hominins, no archaeological remains, no bones, and no tools. No one has discovered remains or artifacts from this mysterious group of hominids. Yet the genetic code that they left within fossils of other hominins, and in living humans too, is offering profound insights into how our species came to be and what the world was like at the time.

Researchers believe that the ghost hominids most likely separated from the common ancestor of modern humans and Neanderthals between 360,000 and one million years ago. Durvasula and Sankararaman (2020) estimated that the ancestors of modern Africans interbred with the mystery humans at some point in the past 124,000 years. The researchers also note that it is possible that humans interbred with several waves of different hominids over thousands of years.

## Interbreeding

Genes from fossils have shown that the ancestors of many living people mated with Neanderthals and with Denisovans. The new

genomic studies rely on complex models of inheritance and population mixing. But, taken together, they build a strong case that even before modern humans left Africa, it was not uncommon for different human ancestors to meet and mate. The gold standard for detecting interbreeding with archaic humans is to sequence ancient DNA from fossils of the archaic group and then look for traces of it in modern genomes. Researchers have done just that with Neanderthal and Denisovan genomes up to 200,000 years old from Eurasia. But no one has been able to extract full genomes from more ancient human ancestors. So population geneticists have developed statistical tools to find unusually ancient DNA in genomes of living people. After almost a decade of tantalizing but unproven sightings, several teams now seem to be converging on at least two distinct episodes of very ancient interbreeding (Gibbons 2020).

## Summary

Humans, among the other living primates, are most closely related to the apes, which include the lesser apes (gibbons) and the great apes (chimpanzees, gorillas, and orangutans). These so-called hominoids – which are the gibbons, great apes, and humans, emerged and diversified during the Miocene Epoch, approximately 23 million to five million years ago. Neanderthals and Denisovans were human populations that separated from the modern lineage early in the Middle Pleistocene. Many modern humans carry DNA derived from these archaic populations by interbreeding during the Late Pleistocene. The evolution of our species from an ape-like Miocene ancestor was a complex process. No one has discovered remains or artifacts from this mysterious group (“ghosts”) of hominids, but researchers believe that they existed. Researchers around the world are expecting to learn more about these ancient humans (Figs. 1, 2, and 3).

## Definition

Behavior exhibited by two or more individuals at the same place and time.

## Introduction

In nature, it is common to observe animals conducting joint behaviors. For example, different animals drinking from the same water source at the same time, roosting together or migrating in flocks are all examples of communal behavior. Communal behavior in its broadest sense does not necessarily imply a benefit for the individuals exhibiting such behavior. In the joint drinking example above, animals may not necessarily benefit from drinking together (drinking alone may be as beneficial). However, in order to evolve, a communal behavior (just as any behavior) is expected to provide benefits that outweigh its costs. Therefore, when individuals preferentially or exclusively exhibit a given behavior communally, this suggests a benefit of sharing this behavior. The benefit may be directly linked to the communal behavior exhibited (for example, communal roosting in birds has thermal benefits that allow individuals to save energy) or it may create the conditions for cooperation among individuals (for example, communal drinking may allow for higher rate of overall vigilance behavior and hence more efficient predator detection).

## Adaptive Value of Communal Behaviors

### Predation Risk Reduction

A classic advantage provided by communal behaviors, such as communal movements, communal feeding, or communal breeding, is that it reduces predation probabilities. This can be by a passive dilution effect as a given individual becomes less likely to be predated since more individuals are available or by increasing the probability to detect a potential predator if more than one individual is vigilant.

### Buffer Against Environmental Variation

In extreme or highly variable environmental conditions, several individuals form clusters. For example, by “huddling” individuals increase their body temperature, which allows them to keep warm while saving energy in thermoregulation (Gilbert et al. 2010). This behavior may therefore effectively reduce the negative effects

caused by the variation in ambient temperature in wild animals.

### Increased Offspring Survival

Biparental care, when both male and female parent care for their offspring, is a form of communal behavior that directly increases the number of offspring reaching independence. Several females, males, or pairs can also share the same nest and often parental duties. Such behavior can be broadly referred as communal breeding or joint nesting and can sometimes increase per female reproductive output (Barbara 1994).

### Communal Behavior and Kin Selection

Communal behaviors are often exhibited among individuals of a same species and, when so, more particularly among genetically related individuals, typically members of a same family. That is because the indirect benefits of communal behaviors, and therefore their probability to evolve, increase as the relatedness between the individuals increase (Gilbert et al. 2010). For example, in cooperatively breeding species, the “helpers” (nonbreeding individuals that assist a breeding pair in caring for their offspring) are often related to that breeding pair (Koenig and Dickinson 2016).

### Communal and Cooperative Behaviors

Cooperative behavior is a form of communal behavior which requires coordination among the individuals to their mutual benefit (McFarland 2014). Cooperation requires active help, whereas a communal behavior, while expected to be beneficial, does not require that one individual actively helps another (i.e., incurring a cost and benefitting another individual). For example, in the communal drinking example, individuals do not help each other in their drinking, but by being together at the water source they are better able to avoid predators. The behavior of watching for predators is cooperative because while an individual is watching it is not drinking. The communal behavior (going down to drink together at the river) is not, but may nonetheless decrease

predation probability by increasing predator confusion or decreasing an individual's chances of being taken by a predator.

### Communal Behavior in Entomology

In the encyclopedia of entomology (Capinera 2008), communal behavior has a slightly more precise definition and is described as “a level of sociality less than eusocial behavior. A type of pre-social behavior. It involves members of the same generation sharing a nest, but without brood care.”

### Communal Behavior in the Social Sciences

In the social sciences, communal relationships describe a behavior providing a benefit to the receiver in response to a need or to demonstrate a general concern for another (Clark and Mils 1993). Therefore, this definition does not require a shared behavior among the focal individuals. For example, a parent caring for an infant is described as a classical communal relationship (Clark and Mils 1993) while such behavior is not a communal behavior in biological sciences since the parent and the offspring do not exhibit the same behavior.

## Definition

In humans, communication is one of those terms that everyone knows but may be a little more difficult for some of us to define. In animal communication, biologists have been arguing over the definition for decades (see Table 1 for some, but by no means exhaustive list, of animal communication definitions). There are three things that most biologists agree upon: (1) there has to be a sender and a receiver, (2) there has to be a signal, and (3) this signal has been shaped by natural selection for the purpose of communication (this last piece becomes important when we start to define cues versus signals below).

Where biologists disagree is the relationship between sender and receiver and what is being transmitted in the signal. The relationship between sender and receiver becomes important when we think about fitness and how natural selection acts on individuals. Dawkins and Krebs (1978) proposed that communication involves a sender manipulating the receiver but failed to take into account that the receiver is also under natural selection and is not a by-stander in the communication relationship. Later, they (Krebs and Dawkins 1984) clarified that, in general, a sender is manipulating the receiver and the receiver is trying to mind-read the sender. Viewed this way, both sender and receiver are under natural selection and both are essentially trying to trick the other into doing something that benefits them. This adaptationist definition was stated best by Maynard Smith and Harper (2003, p. 3) where they defined communication as: “a sender producing a signal, which alters the behavior of other organisms, which evolved because of that effect, and which is effective because the receiver’s response has also evolved.” This takes the sender and receiver into account, clearly defines a signal, and allows for natural selection to act on the sender and receiver. The next thing most biologists disagree on is what, if anything, is being transferred between sender and receiver in a signal.

The Role of Information in Communication

The idea that information is transferred between the sender and receiver is incorporated either explicitly or implicitly into many definitions of animal communication (Table 1). Information, like communication, is a word everyone knows but is difficult to define. For this reason, some biologists have raised issue with the use of the word information in the formal definition of animal communication (Owren et al. 2010; Scott-Phillips 2008). Formally, information is assumed to have been transferred when a signaler influences the behavior of a receiver. As Searcy and Nowicki (2005, p. 207) note, “The sole value of a signal to a receiver is as a source of information, information that it uses in choosing the behavioral, physiological, or developmental responses that will maximize its fitness.”

The amount of information transferred can be quantified, in bits, as a reduction in uncertainty to the receiver following a communication exchange

(Shannon and Weaver 1949). For instance, if a female bird is trying to select a potential mate, she has to determine whether a bird singing near her is the correct species, the correct sex, and potentially of the highest quality. Thus, signals produced by the signaler contain potential information about species, sex, and quality and this helps the female reduce her uncertainty when making a mate-choice decision. This definition is useful insofar as it permits an objective description of the value of information. Yet, few studies ever quantify the information content of animal signals; rather, the information content is assumed to exist and thus have value. By contrast, Scott-Phillips (2008) argues that Maynard Smith and Harper’s (2003) definition of communication does not use the word information and thus, information is unnecessary in a definition of communication. But is assuming that such information exists useful?

Owren et al. (2010) had some additional arguments against the use of information, in particular “encoded information,” in the formal definition of

Communication, Table 1 Some key definitions of animal communication

| Definition                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    | References                      |
|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------|
| Communication occurs when the sender does something that appears to be the result of selection to influence the sensory organs of the receiver so that the receiver’s behavior changes to the advantage of the sender                                                                                                                                                                                                                                                                                                                                                         | Dawkins and Krebs (1978)        |
| Building off of their definition in 1978: Communication is based upon manipulation and mindreading. They coevolve and signals are the result of this coevolution                                                                                                                                                                                                                                                                                                                                                                                                              | Krebs and Dawkins (1984)        |
| Communication involves a sender producing a signal, which is “any act or structure which alters the behavior of other organisms, which evolved because of that effect, and which is effective because the receiver’s response has also evolved” (p. 3)                                                                                                                                                                                                                                                                                                                        | Maynard-Smith and Harper (2003) |
| Signals are characteristics fashioned or maintained by selection because they convey information to a receiver                                                                                                                                                                                                                                                                                                                                                                                                                                                                | Searcy and Nowicki (2005)       |
| Signals are stimuli produced by a sender and monitored by a receiver to the net benefit of both parties and have evolved for the purpose of relaying information                                                                                                                                                                                                                                                                                                                                                                                                              | Bradbury and Vehrencamp (2011)  |
| Communication is “the use of specialized, species-typical morphology or behavior to influence the current or future behavior of another individual” (p. 771)                                                                                                                                                                                                                                                                                                                                                                                                                  | Owren et al. (2010)             |
| A signal is “any act or structure that (i) affects the behavior of other organisms; (ii) evolved (or is maintained) because of those effects; (iii) is effective because it transfers functional information to receivers” (p. 663)                                                                                                                                                                                                                                                                                                                                           | Carazo and Font (2010)          |
| “Communication occurs if trait values of one organism (the informer) stimulate the sensory systems of another organism (the perceiver) in such a way as to cause a change in the behavior of the perceiver (compared to a situation where the trait values of the informer were different). We use ‘communication’ in the narrow sense of applying only to traits that were selected for their communicative function (that is, to signals). Thus, communication in this sense is sometimes called signaling and sometimes true communication (c.f. inadvertent information)” | Ruxton and Schaefer (2011)      |

animal communication. First, they argued that because biologists cannot agree on a definition of information in an animal communication context, using the word information creates nothing but ambiguity and a lack of testable hypotheses grounded in evolutionary biology. They continue to argue that Shannon and Weaver's definition of information (the correlation between the occurrence of one event with the occurrence of another event (Shannon and Weaver 1949)) cannot be applied to an animal communication definition that contains the idea of encoded information because it implies a "meaning or a significance of that event" (Owren et al. 2010, p. 761). Second, they argued that the use of encoded information implies a cooperative co-evolution between sender and receiver because if a sender encodes information in its signal there must be a benefit to the sender for sharing that information. Third, they argued that using the idea of encoded information puts the proverbial carriage before the horse in our understanding of the evolution of language. Instead, they suggest a definition where the sender influences the receiver and the concept of information is explicitly excluded (Table 1).

In response to these concerns about the inclusion of information in the formal definition of animal communication came a flurry of responses arguing for the inclusion of information in the definition (Carazo and Font 2010; Ruxton and Schaefer 2011; Seyfarth et al. 2010). Among other things, the respondents noted that, by focusing solely on the sender's influence on the receiver, the important role of the receiver is downplayed, which is a problem given that the receiver is an entity that is also subjected to selection. Thus, researchers seem to have circled around to the original issue: what is the role of the receiver in a communication exchange? To date, there has not been a consensus but the conceptual idea of information has value, even if it is rarely quantified, and even if many definitions of communication do not require it to be explicitly defined.

And for the purpose of this entry, we adopt a recent definition by Carazo and Font (2010, p. 663): a signal is "any act or structure that

(i) affects the behavior of other organisms; (ii) evolved (or is maintained) because of those effects; (iii) is effective because it transfers functional information to receivers." The Carazo and Font definition includes the manipulative or influential aspect of the sender on the receiver (i), it defines a signal (ii), and it acknowledges the receiver's role in the communication scheme and that, even if not intentional by the sender, information from the receiver's perspective may be obtained (iii).

## Signals Versus Cues

There is a formal but important distinction between signals and cues. Cues, like signals, modify the behavior of a receiver, but cues have not evolved specifically for the purpose of communication (Bradbury and Vehrencamp 2011; Scott-Phillips 2008). Rather, cues are attributes of or associated with other organisms that provide information to the receiver and, hence, influence the receiver's behavior. For example, when an owl uses the movement of the grass caused by a mouse foraging, the owl is using a cue not a signal because the movement of the grass has not evolved specifically for communication with the owl; rather, it is a by-product of the mouse's foraging behavior. Yet cues, like signals, may provide sources of information.

## Signal Modalities and Types

With this definition of animal communication (and the distinction between a signal and cue), the amazing diversity illustrated by animal communication systems can be explored. Animals communicate using visual, acoustic, olfactory/chemical, tactile/seismic, and electrical signals (Bradbury and Vehrencamp 2011). Furthermore, signals vary on a continuum of conspicuousness from subtle, close-range, direct signals to obvious, long-distance, broad audience signals (Laidre and Johnstone 2013). Each of these has a different active space – the effective range through which a signal can work, each is differentially

localizable, and each has constraints on the rapidity with which they vary, which has implications on the maximum amount of information transmitted. Thus, the specific modality employed may depend on the habitat in which it must be used as well as constraints on signal propagation.

Visual signals, perhaps one of the more conspicuous modalities to humans, can include colors, patterns, and/or movements. An example of color, pattern, and movement all being used together comes from the mating dance of the bird-of-paradise Wahnes's parotia (*Parotia wahnesi*) from Papua New Guinea. Males flash their multicolored, patterned iridescent chest at females, while hopping around and moving the ornaments attached to their head (see <https://macaulaylibrary.org/video/469253> for a video). The active space of a visual signal will be reduced in areas with physical obstructions, but because they can be dynamically varied, they can potentially transmit a lot of information.

Acoustic signals, another conspicuous modality to humans, include different frequency, temporal, and amplitude patterns and are thus an excellent example of signals that vary in their conspicuousness. Unlike visual signals, some of which, like color, can sometimes be “always on,” acoustic signals are by default off until they are produced. Two examples of acoustic signals on the opposite ends of the conspicuous spectrum come from birds. Many bird species have a “whisper song” or a “soft song” that is quiet and meant for close range communication between a male and female breeding pair. By contrast, mobbing calls are predator-elicited acoustic signals designed to be heard by both the predator and conspecifics. Mobbing calls are generally broadband and harsh in their acoustic structure making them very conspicuous and able to travel long distances to many receivers. Acoustic signals can travel around visual obstructions and may have large active spaces (the low frequency elephant and whale vocalizations can travel many kilometers). Because they may be rapidly modified, they can contain a substantial amount of dynamically varying information. Human language, after all, is not communicated using olfactory signals for a reason.

Chemical signaling may be the oldest method of communication (Bradbury and Vehrencamp 2011). Humans detect chemical signals both by taste and smell. Chemical signals tend to be long-duration signals because they have a slower diffusion rate (although this can be environmentally dependent and different components of chemical signals vary in their volatility (Parsons et al. 2017). An example of chemical signaling is the track that ant species lay down to allow nest mates to follow their tracks to locate food. These chemicals are species and ant colony specific. A recent realization is that the odorants used in chemical signaling may be produced by symbiotic bacteria living on or in animals.

Tactile or seismic signaling can be more difficult to define. For example, if in a male-male contest one male pushes the other, is this considered a signal? In other systems, it is easier to define. For example, in spider courtship, the males will pluck the strings of their web to communicate to the female and the foot drums of kangaroo rats contain information about individual identity that are transmitted to others within seismic range.

Some fishes (knifefish, elephant fish) are able to create electrical signals with specialized electric organs. These signals are used in territory and aggressive interactions, courtship, dominance, social coordination, and identification (reviewed in Bradbury and Vehrencamp 2011). More species seemingly are sensitive to other species' passive electric discharges. For example, short-beaked echidnas (*Tachyglossus aculeatus*) have electroreceptors on the tip of their snout that they forage with to detect prey, but it is unknown if echidnas use this sensory ability for communicative purposes (Bradbury and Vehrencamp 2011).

## What Influences Signal Transmission?

Given these possible modalities, what determines the conditions under which a specific modality is used and how it transmits? Animals are constrained on the signals they can send based on the environments they live in and based on their own abilities to produce and receive

potential signals. Endler (1992) coined the term “sensory drive” to recognize the inevitable relationship between environmental conditions, the sensory systems, and signals that work together to drive the evolution of signaling systems.

The medium in which the signal is produced can dictate choice of signal modality. For example, electric signals are used only in aquatic environments because water increases the active space of potential signals. Within a modality, the medium can have drastic effects on signal transmission and diffusion. For example, acoustic signals travel farther in water than in air.

Signals may be blocked or otherwise masked by environmental noise. For example, broad-spectrum water noise masks acoustic signals. Torrent frogs (*Odorrana tormota*) living near rapidly flowing, noisy streams in China have escaped this constraint by producing what we perceive as ultrasonic (very high frequency) signals that are able to communicate above the lower-frequency water noise. Birds vocalizing in a cicadia-filled forest or in an urban environment with road noise may shift the frequency of their songs or calls to avoid environmental masking.

Within a medium, signals both attenuate (lose amplitude and become more difficult to detect) and degrade (lose fidelity) when transmitted over space. For acoustic signals, Morton (1975) formalized this into the acoustic adaptation hypothesis where he predicted terrestrial acoustic signals will be structured to maximize transmission within the habitat they are produced. For long-distance acoustic signals, there is a small effect of the acoustic environment on signal structure. The best support for the hypothesis comes from large-scale comparative analyses of birds or studies that look at a single species across a range of environments. The effects of the environment effect signal design in other modalities as well. For example, in a paper discussing visual signals and environment, Karen Marchetti found that *Phylloscopus* warblers vary in their color patterns depending on the light intensity of their habitat with brighter species living in darker habitats (Marchetti 1993).

Finally, the sensory systems of both the sender and receiver will influence the signal modality and

signal structure. Senders physiologically need to be able to produce a signal that receivers can perceive and process and thereby evolutionary influence the signal structure through their response (Endler 1992).

## Multimodal Communication

The examples of signals so far focus on a single modality. However, in reality, multimodal communication, where a sender uses signals from two or more different sensory modalities, may be relatively common. This section will discuss the evolution, use, and prevalence of multimodal signals in animal communication.

Why use a multimodal signal over a unimodal signal? After all, producing more than a single signal is assumed to be more costly than producing one. The two main hypotheses to explain the evolution of multimodal signaling are to increase content/reliability (i.e., content-driven selection; Hebets and Papaj 2004 or the multiple messages hypothesis; Johnstone 1996) and/or to increase robustness (i.e., efficacy-driven selection; Hebets and Papaj 2004 or the back-up signals hypothesis; Johnstone 1996). These ideas were formalized into a framework by Sarah Partan and Peter Marler in 2005 to describe redundant versus non-redundant multimodal signals (Fig. 1).

Redundant signals contain the same information in the signal components where non-redundant multimodal signals contain different information in their components. Apply this to the mechanisms suggested above and redundant signals may be used to increase robustness because if one modality is blocked, the information will still reach the receiver (back-up signals hypothesis). Whereas nonredundant signals may be used to increase information content because the signals contain different information (multiple messages hypothesis).

Furthermore, within redundant and non-redundant multimodal signals, Partan and Marler (2005) considered the inter-signal relationship or how the components within a signal may interact from the perspective of the receiver. For example, in the model organism of the fruit fly (*Drosophila*

| Redundancy    | A        |  | A + B    |                                                                                         | Equivalence  |
|               | B        |  | A + B    |                                                                                         | Enhancement  |
|               |          |                                                                                   | A + B    |                                                                                         | Antagonism   |
| Nonredundancy | A        |  | A + B    |  and  | Independence |
|               |          |                                                                                   | A + B    |                                                                                         | Dominance    |
|               | B        |  | A + B    |  or  | Modulation   |
|               |          |                                                                                   | A + B    |                                                                                         | Emergence    |

*melanogaster*), Fanny Rybak and colleagues found that males that use both an acoustic and a chemical component in their female courtship display have more successful matings than males that use only acoustic or chemical components (Rybak et al. 2002). This illustrates redundant enhancement (Partan and Marler 2005; Fig. 1), where both components provide information to assess male suitability (redundant), but when combined males have significantly more matings than from either component presented alone (enhancement).

Multimodal signaling, just like unimodal signaling, is subject to sensory drive and also is subject to selection for reliability. For example, Anne Leonard and colleagues focused on plant-pollinator signaling systems where most plants use both visual (color) and chemical (olfactory) signals to communicate nectar rewards to their pollinators (Leonard and Masek 2014). Selection for increased information and reliability about the nutritional reward (content-driven selection and robustness against a noisy background with multiple olfactory and visual signals bombarding pollinators (efficacy-driven selection) may increase the benefits from multimodal signals over unimodal signals.

Much of the research on multimodal communication has focused on intraspecific signaling systems, mainly antagonist and mate-choice signals.

Yet, signaling systems can also exist across species. Many aspects of multimodal signaling systems are expected to be similar within and across species, and signal reliability underlies all signaling. Interspecific communication systems have an additional component that must be considered: the need for overlapping sensory systems, sensory thresholds, and cognitive abilities. As discussed above, the sensory systems and the threshold limits within those sensory systems are important for intraspecific signaling as well. However, in general, individuals of the same species share the same sensory system, thresholds, and cognitive abilities. Therefore, when examining interspecific signaling systems, researchers need to be especially aware of the sensory systems of each species involved to understand the signaling system as a whole. As research expands into multimodal signaling systems, researchers are beginning to discover that not only are most signaling systems multimodal, but that they often consist of three and potentially even four different modalities.

**Signal Reliability and the Evolution of Signals**

To be useful to a receiver, signals must be reliable. Because selection acts on both the sender and the

receiver, reliability must be considered from both the sender's and receiver's perspectives. By ignoring unreliable signals, receivers select for signals that contain reliable information. However, no signaling system is honest or reliable 100% of the time. Signals can be unreliable in two ways: they can unintentionally not be linked to a stimulus (false signals) or intentionally presented in the absence of the stimulus (deception) (Searcy and Nowicki 2005). For example, white-winged shrikes (*Lanio versicolor*) emit alarm calls to the rest of the mixed-species flock when they detect predators. This causes the rest of the flock to cease foraging and dive for cover. This species also emits deceptive alarm calls to manipulate the rest of the flock to dive for cover permitting them to forage without competition (Bradbury and Vehrencamp 2011). Whereas these alarm calls are sometimes deceptive and not completely reliable, the signaling system persists. Therefore, the mantra of signal evolution is that signals are honest or reliable *on average* (Searcy and Nowicki 2005).

Signals are often kept honest or reliable through production costs. The magnitude of the cost needed to keep a signal reliable is often dependent on the relationship between the sender and receiver. If the sender and receiver have aligned interests, the signal needs to be less costly because the aligned interest alone can maintain honesty because the fitness benefits are linked between sender and receiver. For example, although often temporary, mobbing signals directed at conspecifics are considered to have few costs because the interest between the sender and the receiver at the time are aligned: work together to drive a predator out of the area. However, as interests start to diverge, senders will be more tempted to provide unreliable information; therefore, the costs should be greater to ensure signal reliability. For example, when males compete, each male's interests are opposed; both want to win the encounter. Signals used in these situations are expected to be costly to ensure reliability, such as seen with the costly antlers of elk and fiddler crab's giant claws. More generally, because sender's and receiver's interests rarely completely overlap, most signals impose a cost

to maintain reliability and honesty (Bradbury and Vehrencamp 2011).

An early explanation for variable costs is from Amotz Zahavi's handicap principle, where signals impose a handicap on the sender to ensure honesty, and not all senders can bear the cost (reviewed in Searcy and Nowicki 2005). They can indicate the quality or condition of the sender. All senders can produce the signal, but only certain individuals can bear the costs of the signal. The costs can be enforced in signal production, development, or maintenance. Production costs can be in the form of energy used in production, time spent signaling and away from other activities or increased conspicuousness to predators. Handicap signals can also have developmental costs. Development costs are born prior to signaling and often direct limited resources to signal development. Carotenoid expression in birds and fish is developmentally costly. Carotenoids must be acquired by foraging and are used in immunological defense systems. Therefore, any animals that can show evidence that they have acquired carotenoids (through carotenoid-dependent coloration) have demonstrated that they forage well and are of both high nutritional and immunological quality. Handicap signals can also impose maintenance costs (Bradbury and Vehrencamp 2011). Maintenance costs refer to the costs of maintaining a signal and can be energetic or act through increasing predation risk.

Index signals are signals that are constrained by the anatomy, physiology, or experience of the sender. Unlike handicap signals, not all individuals can produce the signal and honesty is enforced not by direct costs but by constraints. They most often indicate condition and quality. For example, song repertoire size in birds with open-ended learning can be considered an index signal because it cannot be faked: repertoire size is contingent on age.

Signals may also have third party costs. Third party costs can come in two forms: reciprocity or as an honesty check. Reciprocity exists in systems where individual recognition is present and previous actions are remembered. For example, allogrooming (the act of one individual grooming and removing ectoparasites from another) in primates

and ungulates is often kept honest through reciprocity: if you do not scratch my back, I will not scratch your back next time. The other form of a third-party cost is when the signal is kept honest by the responses of other individuals. For example, the songs that male brown-headed cowbirds use to attract females are maintained by other male cowbirds. Males are attacked more when they sing the female-preferred interphrase unit, which means only strong males can endure being attacked, and the signal is kept honest through these checks (reviewed in Searcy and Nowicki 2005).

### Signal Design and the Evolution of Signals

Now that we understand how a signaling system evolves and is maintained, how do the signals themselves evolve? Darwin thought deeply about the evolution of communication in his book *The Expression of Emotions of Man and Animals* and many of his ideas persist (Darwin and Prodger 1998). For example, his principle of antithesis is that aggressive and submissive displays will be structured so that they will be opposite each other. The examples illustrated here may be extensions of behaviors used when approaching or retreating.

The early Ethologists viewed signals as evolving through a process called “ritualization.” Ritualization is the process by which a nonsignal (such as a cue), used in a particular context, becomes predictive of what follows and then becomes exaggerated or stereotyped so that what follows becomes clear. Ritualization involves formalizing parts of a movement pattern. Ethologists would refer to these parts as “intention movements” not because the animals intend to do something, but rather because those movements predict (to us at least) what will follow.

Some of the displays that Darwin thought about when coming up with his principle of antithesis can be explained as having evolved through the process of ritualization. Ruffling feathers before flying away might be an intentional movement that the sparrow ritualized into a submissive display. Putting the ruff up to increase apparent size and protect

its neck might be an intentional movement that dogs used that later became ritualized into an aggressive display. Other sorts of examples include: breathing (a nonsignal) becomes ritualized into courtship song; a defensive posture (imagine a dog crouching down) becomes ritualized into a submissive signal (imagine that same dog crouching down after it has gotten caught eating your shoe); autonomic nervous system processes such as piloerection or feather ruffling often provide the source of the ritualized display. At that level, many ritualized signals may be honest indicators of how the animal perceives the world at that time. Ritualization should be straightforward to evolve because the signaler is already producing something that the receivers respond to in its own best interest.

This ritualized view of communication underlies the idea that communication functions to provide unambiguous information. However, because ritualization removes information by removing variability, once ritualized, additional signals are needed to emerge to provide more information. Thus, you could envision elaborate courtship rituals evolving by the process of ritualization of signal after signal. Cumulative selection like this is how we generally view the evolution of all sorts of complex traits.

But how do signals and signal receptors actually evolve: probably by a series of incremental fitness gains? Most are likely to be “exaptations” evolved from traits that already have some function but become specialized for another. Each step of a complex signal probably involved an incremental benefit and the potentially lengthy process of cumulative selection was driven by the fitness benefits of having a particular trait at each step of the way. Through these incremental fitness benefits, we can envision scenarios by which rather complex signals evolve.

There may be preexisting biases that make certain modalities or types of signals more likely than others. For instance, females of different taxa (some birds, some fish) find males with long tails particularly attractive, and studies of sword-tailed fish find that even in the absence of swords in a clade, sword-bearing fish are still found more attractive.

Structure is likely to reflect function. Thus, avian mobbing calls should be easily localizable if animals are to recruit others to help mob. Similarly, they should be broadband to ensure predator-directed mobbing calls are actually perceived by the predator. The mobbing call is much wider bandwidth than the avian aerial alarm “seet” calls. But even alarm calls will vary in their localizability. Bird alarm calls to terrestrial predators tend to be wider bandwidth and more localizable than those given to aerial predators. One possible explanation of this has to do with risk. Aerial predators move faster and generally are associated with a more compelling risk than terrestrial predators. Remember, not all animals call, nor do most animals call when they are really exposed to imminent predation (unless it is given to scare the predator into dropping them).

Thus, we see some convergence in the structure of aerial alarm calls in birds. Many songbirds produce similar calls when they detect raptors. This convergence in structure reflects convergent problems – warning others while not getting preyed upon themselves. The convergence works because of how the calls are structured. They fade in and fade out and are relatively high frequency as Peter Marler first pointed out in the late 1950s. The combination of fading in and fading out both in volume and also in their structure makes them relatively hard to localize. Rapid and sharp onsets are easier to localize than narrow-band, smoothly fading in sounds. Additionally, because they are high frequency, they transmit less than a lower frequency call of the same structure. Thus, birds can better target their recipients – and not advertise the fact that they have seen a raptor to all – including to the raptor. Additionally, call frequencies used are outside the best hearing range of some of their predators. Taken together, these similar selective pressures might lead to convergent call structure.

### Functionally Referential Signals

In addition to containing information that helps animals make decisions, calls may be said to have referential meaning. The referential meaning of

signals has been most studied in alarm communication and in food calls.

Alarm calls are signals emitted when an animal detects a predator. For species that emit situationally variable alarm calls, two hypotheses have been invoked to explain the meaning of variable calls. Alarm calls may vary according to the “response urgency,” or imminence of predation, the caller faces. Thus, short calls may be produced when predation is imminent while longer calls may be produced when there is more time to assess and manage the risk of predation. By doing so, calls may communicate the degree of risk the caller experiences and may be a function of the caller’s arousal. Alternatively, different alarm calls may denote different types of predators (e.g., aerial vs. terrestrial predators), or even the exact species of predator. These alarm calls are known as “functionally referential” in that the calls refer to specific external stimuli. Labeling a specific external object or event is known as “referential communication.” Such referential communication is a required component of human language and therefore is of some interest. Philosophers debate what referential communication really entails. Does it mean that animals form “images” of objects? Does it require labeling (eagle!) or could it communicate the desired action (run up a tree now!)? Does it require complex cognitive abilities? Honeybee waggle dances, after all, communicate very specific information about the quality of food, the distance to the food, and the direction to the food. Is there any biological basis for saying that referential communication in monkeys is more complex than in bees? Some researchers care about this because they would like to use human language abilities as a metric by which to contrast humans with other species. If bees and monkeys share the same abilities, then perhaps humans are not that cognitively complex. Rather than engaging in this debate, Peter Marler, Chris Evans, and Marc Hauser shifted the discussion by defining the term “functionally referential” (reviewed in Evans 1997). Functionally referential makes no reference to higher-level cognitive processes but rather focuses on production and response specificity. Thus, to quantify referential communication, it is

essential to have a high degree of production specificity – specific calls are elicited by specific predators, and it is essential that receivers respond uniquely to these calls; thus, the calls are contextually independent from the receivers perspective.

Vervet monkeys studied in East Africa (Uganda and Kenya) are a well-studied system of referential signaling. Classic work by Peter Marler, Dorothy Cheney, and Robert Seyfarth showed that monkeys produce acoustically different calls in response to different types of predators: they “chutter” to snakes, “bark” to leopards, and “cough” to eagles. Monkeys hearing chutters immediately stand bipedally and look for snakes, those hearing barks climb trees and retreat to the distal part of limbs where they will be safe from leopards, and those hearing coughs retreat to the center of trees where they are safe from eagles (Seyfarth et al. 1980). But do these signals really communicate predator type? The calls could signal information about predator behavior or act to instruct receivers about the appropriate response. These would not be referential in the same sense. For reasons like this, some have questioned the utility of using the term referential. Furthermore, recent work by Nicholas Ducheiminsky, Peter Henzi and Louise Barrett with a different subspecies of vervets in South Africa has even questioned the inferences from earlier vervet studies (Ducheiminsky et al. 2014). South African monkeys living in larger groups and under different predation risks did not have the contextual independence seen in East African vervets. If we accept that cognition is a trait subject to selection, we should expect both intra- and inter-specific differences in cognitive abilities based on their value. It is likely that the different conditions that the South African vervets lived under selected for different cognitive abilities.

Food calls are vocalizations emitted around food. Are they referential? Can they label specific types of food in ways that animals may label types of predators? The short answer is that food calls are rather complex and multipurpose. Food calls are given in both feeding and nonfeeding situations. Most species do not produce unique calls for different foods. The most common mechanism associated with food variation is changing the

calling rate, suggesting that call structure reflects the caller’s internal state rather than the food type. Additionally, there is no unifying function of calls either. Some food calls are used in situations where individuals recruit others to reduce predation risk. Some food calls seem to be used to build a reputation or to attract mates. Some food calls signal ownership of a resource and function to reduce competition. Thus, whereas alarm calls may be referential (or not), most food calls are not referential.

## Intraspecific Communication

Individuals may communicate with conspecifics for a variety of reasons. We will explore a few of the contexts that involve intraspecific communication, including the sexually selected signals used in antagonistic and mate attraction contexts, signals under kin selection, and finally social calls. It is important to reiterate that just because the sender and receiver are from the same species, interests need not be aligned because selection acts on the individual, not the group or the species.

As mentioned, antagonistic and mate attraction signals are under sexual selection, which is the evolutionary process that arises from the competition of one sex for the other. In most mating systems, males are competing for females (although there are some interesting polyandrous examples such as jacanas and a more contemporary view of mate choice recognizes that both individuals are making decisions about whom to mate with). In antagonistic contexts, including contests over mates, territories, or rank, the interests of a sender and receiver are opposed. Therefore, we expect high signaling costs to ensure honesty. Male weapons which are (often exaggerated) structures used to defend territories or females are an excellent example of high costs. Most weapons (such as antlers) are expensive to carry, produce, and/or maintain and not all males have the required nutritional history, genetic quality, or a large enough body size to support growing a weapon (Emlen 2008). These weapons are used as both assessment signals of male fighting condition or quality as well as in combat. In

general, the male with the biggest weapon usually wins.

Mate attraction also has diverging interests between males and females because of unequal investment in reproduction (females often, but not always, invest more). There is often a tradeoff between the signal and another function to ensure reliability. Many signals used in mate attraction are often correlated with some sort of information about the male: condition, foraging ability, parental care. Similar to antagonistic signals, these signals may become exaggerated by sexual selection. For example, the satin bowerbird (*Ptilonorhynchus violaceus*) builds an elaborate structure (called a bower) (<https://macaulaylibrary.org/video/456303>). Research by St  phanie Doucet and Robert Montgomerie suggests that both a male's bower quality and his ultraviolet coloration are correlated with his condition suggesting that these signals are reliable signals of male quality (Doucet and Montgomerie 2003).

Communication between kin is another common communication context. In general, when kin communicate with other kin or their parents, interests mostly overlap because of genetic relatedness. There are two types of signals that have received the most attention: begging calls by offspring and alarm calls. In birds, begging calls appear to be honest signals of need and parents respond appropriately (Searcy and Nowicki 2005). Due to the genetic relatedness and aligned interests between parents and offspring, there may not need to be heavy costs to ensure signal honesty. In fact, researchers have found only weak support for energetic or predation costs that could maintain honesty. Alarm calls are another area of research where interests, especially between kin, may be aligned. Alarm calling behavior is common in birds and mammals and usually conveys information about the predator to conspecifics (and, as we will discuss later, to heterospecifics). In species that live in family groups, this apparently altruistic behavior is often explained by kin selection: an individual gains a fitness benefit by helping a genetic relative. For example, research by Michael Griesser with Siberian jays (*Perisoreus infaustus*) has shown them to be

more vigilant and more likely to give alarm calls in the presence of kin than nonkin (Griesser 2003).

Many species live in groups. Social calls among conspecific group members may facilitate group cohesion, group predator avoidance (alarm calls), and/or group foraging (food calls). Because most individuals will benefit from being in a group when groups form to reduce predation risk, interests are more aligned than opposed and, therefore, costs on signals to retain reliability should be relatively low. Food calls, where an individual attracts others to a food source, are thought to be advantageous to the sender and receiver because the group will have reduced predation and/or the additional individuals will help form a coalition to defend the food source from others. This is thought to be the case in ravens (*Corvus corax*). Raven pairs hold territories and when a nonresident raven discovers a food source on the pair's territory, it will give food calls to attract other nonresident ravens to the food source to help defend it from the resident pair (reviewed in Searcy and Nowicki 2005).

## Interspecific Communication

Individuals from different species (even from different taxa) also communicate. Just like with intraspecific communication, the fitness benefits to both sender and receiver need to be considered as well as the signal reliability. Much interspecific communication involves eavesdropping – the use of a signal intended for another receiver. Eavesdropping by unintended receivers can be an important selective force on signal modality and structure. We might initially assume that the eavesdropping receiver always benefits (otherwise why would they eavesdrop?). However, as with all inter-species interactions, eavesdropping can be positive (+), neutral (0), or negative (–) to the sender. In alarm call signaling systems, the sender generally benefits from having eavesdroppers on their alarm signals because these unintended receivers often assist in mobbing the predator from the area (sender +, receiver +; i.e., social eavesdropping; Peake 2005). When

making habitat selection decisions, many species eavesdrop on conspecifics' breeding success to make decisions about territory and nest site location the following breeding season with little to no effect on the sender (sender 0, receiver +; i.e., social eavesdropping; Peake 2005). Some species also eavesdrop on heterospecifics. Finally, eavesdropping receivers can have a negative impact on the sender (sender –, receiver +; i.e., interceptive eavesdropping; Peake 2005), which would select for less conspicuous and more direct signals. For example, formative work by Michael Ryan and colleagues with Túngara frogs has also found that fringed-lipped bats (*Trachops cirrhosus*) use the “whine-chuck” call of male Túngara frogs to localize them. Like conspecific females, the addition of the “chuck” makes it easier for the bats to locate the calling individual. Therefore, there is a cost to producing the female-preferred “chuck” and not all males produce it. It is thought that this predatory cost may in part keep this signaling system reliable (Halfwerk et al. 2014). It is important to note that eavesdropping also takes place within intraspecific communication systems.

As demonstrated in some of the examples we present in this chapter, communication is rarely a private conversation, but rather exists in a communication network with multiple senders and receivers. A communication network is a group of animals (conspecifics, heterospecifics, or both) that are within signaling and receiving distance from one another (McGregor 2005). As with eavesdropping, the costs and benefits of multiple senders and receivers within a communication network will influence the signal. Furthermore, communication networks are not filled with symmetrical contributions across individuals or species. For example, Randler and Vollmer (2013) identified asymmetrical responses across species in a European avian mobbing communication network. Species responded most to conspecific mobbing, but responses to heterospecifics varied across species with chaffinches (*Fringilla coelebs*) having the lowest responses and blue tits (*Cyanistes caeruleus*) having the greatest. Again, the costs and benefits to the sender and receiver must be considered to understand the

complex responses that exist within communication networks. Additionally, as with eavesdropping above, communication networks also exist in intraspecific networks as well.

We initially discussed the idea that both sender and receiver should benefit in order for a signaling system to persist, but that these benefits can occur independently of each other (e.g., sender manipulates receiver, receiver gains inadvertent information). However, sometimes the benefits of the sender and receiver are linked, such as in mutualisms where one benefits if the other benefits. For example, in Kenya, Anne Rasa found that dwarf mongooses and various hornbill species have a communicative mutualism. Dwarf mongooses (*Helogale parvula*) rely on two species of hornbills (*Tockus* spp.) to be vigilant of predators and give alarm calls while they forage, and hornbills rely on foraging mongooses to displace insects during their foraging for the hornbill's consumption (Rasa 1983).

Remarkably, predators and their prey often communicate with each other. Aposematic coloration is the bright coloration and patterning that (when not a Müllerian mimic) is associated with unpalatability. Bright coloration (and often accompanying odors) is easier to learn by predators avoiding prey. This is still a sender + receiver + interaction because the prey does not get eaten (+) and the predator does not get harmed trying to eat an unpalatable prey (+).

## Applied Communication

People have been applying knowledge of communication to manipulate animals' behavior for a long time. Waterfowl hunters mimic their prey's calls, carnivore hunters mimic the sounds that carnivore's prey emit, and now, even fishers can use electronic baitfish (<https://www.livingstonlures.com/>) to attract their prey. But wildlife managers are also using the sounds that animals produce to attract and to potentially repel individuals.

Playbacks of conspecific vocalizations induce preferential settlement in several species of birds (pied flycatchers – *Ficedula hypoleuca*, Laysan

albatrosses – *Phoebastria immutabilis*) and a grasshopper (*Ligurotettix coquilletti*). These studies, and others, suggest that conspecifics may have an important impact on where animals settle and, more generally, that knowledge of conspecific attraction can help inform conservation and wildlife management.

On the Fort Hood Army base in Texas, the endangered black-capped vireo (*Vireo atricapilla*) was having limited success rearing offspring because their nests were parasitized by brown-headed cowbirds (*Molothrus ater*). Cowbirds lay their eggs in other species' nests and this parasitism has caused the decline of many species that cannot evolve the ability to reject cowbird eggs. Wildlife managers Michael Ward and Scott Schlossberg wanted to see if they could call in birds to settle on areas that were "safe" because the researchers were controlling cowbirds in specific areas. To study this, they conducted a playback experiment. In 2000, they had no call playbacks. In 2001 and 2002, they broadcast the vocalizations of black-capped vireos. They found that vireos were attracted and settled in areas with vireo playbacks and were less likely to do so in years and at locations without vireo playbacks. Thus, for black-capped vireos, it seems conspecifics may be important cues for habitat quality (Ward and Schlossberg 2004).

Knowledge that a species uses conspecifics as cues for settlement decisions can inform conservation programs. For instance, animals could be "seeded" into suitable habitat to attract others, or artificial cues could be broadcast or placed in appropriate habitat as a way to attract others. Ultimately, it may be possible to attract enough individuals to form a sustainable population.

Acoustic repellents have been less successful. Repellents can simply be painful sounds or biologically meaningful sounds used by managers to keep animals away from an area. For instance, to reduce bird strikes on airplanes, managers often shoot blanks to scare away birds from runways. Although painful sounds may work, the meaningful ones – including the sounds of predators – have been less successful. However, a series of studies led by Michael Clinchy and Liana Zanette, in a variety of habitats and locations around the world, have

shown that broadcasting the sounds of predators can have remarkable effects on the reproductive success of residents (it goes down), on the foraging behavior of prey (they are more cautious), and on the overall structure of ecological communities (they are changed) through the indirect effect of manipulating perceived predation risk (Zanette et al. 2011). Such manipulations may be an essential tool in reinstalling fear into communities where key predators have been extirpated.

## Conclusions

Animal communication involves some of the most conspicuous behaviors in the animal kingdom. There are numerous ways to communicate as well as numerous contexts for communication. We have provided a brief overview of some of the ways and contexts that animals communicate. We have discussed the importance of signal reliability in maintaining signaling systems. Signals need to be reliable on average in order to be useful and this reliability is often maintained through costs that vary in severity depending on the alignment of interests between sender and receiver. We have discussed how signals evolved and some of the selective pressures that may lead to more complex signaling systems (e.g., multimodal signaling). Animal communication is an active area of research, and there remain many unanswered questions regarding both the evolution and ecology of signaling systems.

## Communication Networks, Eavesdropping, and Audience Effects

Luke C. Larter

University of Texas, Austin, TX, USA

### An Introduction to Communication Networks

Animal communication involves a signaler sending a signal that is perceived by one or more receivers (Bradbury and Vehrencamp 1998). Individuals can be both signalers and receivers and may be both simultaneously. Many studies of animal communication approach the topic from the perspective of signaler-receiver pairs; however, communication in the wild is rarely confined to a single interacting pair. There is a growing acknowledgement that communication most often takes place within communication networks in which multiple individuals are within signaling and receiving range of one another, and these networks can include both conspecifics and heterospecifics (McGregor 2005). The dynamics of communication networks can have profound effects on the evolution of signal form, signaling strategies, and social behavior.

### Eavesdropping

Eavesdropping is a phenomenon that occurs within communication networks. It involves an individual gaining information about a signaler, or two or more communicating individuals, by observing signaling behavior intended for other receivers (Peake 2005). Eavesdropping may yield

costs, benefits, or neither for the signaler, receiver, or the interacting pair being eavesdropped upon. Eavesdropping can be broadly broken down into two categories: *interceptive eavesdropping* and *social eavesdropping*.

#### Interceptive Eavesdropping

When a signaler sends a signal to their intended receiver, but this signal is also received by an unintended receiver, this is an example of interceptive eavesdropping (Peake 2005). Conspecifics may engage in interceptive eavesdropping; however, interceptive eavesdropping has most often been demonstrated as performed by heterospecifics in the contexts of (i) predators and parasites eavesdropping on the courtship signals of prey species to consume signalers or infest them with their progeny (reviewed in Zuk and Kolluru 1998) and (ii) one species eavesdropping on another species' alarm calls (reviewed in Magrath et al. 2015). Thus, interceptive eavesdropping is most commonly a feature of interspecific communication networks (Peake 2005), and the costs or benefits of such interceptive eavesdropping can vary greatly for signalers depending on the identity and motives of the eavesdroppers.

#### Eavesdropping by Predators and Parasites

Signals can be sent in multiple sensory modalities, and examples of interceptive eavesdropping have also been demonstrated in multiple modalities. The most common information that is gained by eavesdropping predators and parasites is simply prey location (Zuk and Kolluru 1998), though predators may also be able to glean information about the profitability of prey animals and the prey animal's local social environment. Below are some examples of interceptive eavesdropping across different modalities:

- (i) **Acoustic signals:** Many of the most famous examples of interceptive eavesdropping are examples in which intercepted signals are acoustic, such as predatory bats targeting calling male túngara frogs (Tuttle and Ryan 1981) and parasitic tachinid and sarcophagid flies targeting various singing insects

(reviewed in Hedwig and Robert 2014). Long-range acoustic signals may be particularly susceptible to interceptive eavesdropping due to their high amplitude, omnidirectional nature, and their ability to be detected day and night (Zuk and Kolluru 1998).

- (ii) **Olfactory signals:** Olfactory communication via airborne pheromones is an important channel for mate attraction and location in many insect species. Males of the southern green stinkbug release pheromones which are attractive to females. These pheromones are also used by female parasitic tachinid flies to home in on male hosts, resulting in high parasitism rates in males (Mitchell and Mau 1971). Such “kairomones” (eavesdropped-upon pheromonal signals) are also intercepted and used to locate host eggs by some egg-parasitoid species (Fatouros et al. 2008).
- (iii) **Visual signals:** In addition to luring hetero-specific males as prey by mimicking females of prey species, predatory female fireflies are also attracted to the bioluminescent signals produced by males of their prey species (Lewis and Cratsley 2008).
- (iv) **Seismic signals:** Seismic signals were long thought to be a communication channel relatively safe from eavesdropping. However, the ability to sense seismic vibrations is taxonomically widespread in arthropods (Cocroft and Rodríguez 2005), and examples of predators and parasites intercepting such signals have been demonstrated. Predatory spiders use the seismic signals of male leafhoppers to locate signalers as prey (Virant-Doberlet et al. 2011), and the egg parasitoid wasp *Telenomus podisi* orients toward the vibratory signals produced by female neotropical brown stink bugs but, interestingly, ignores those produced by males (Laumann et al. 2007).
- (v) **Multimodal signals:** Multimodal signals are thought to evolve because they can transmit information to receivers more reliably or effectively and/or send different kinds of messages simultaneously (Partan and Marler

1999). However, this means that signals may also be more effectively transmitted to eavesdroppers. Predatory jumping spiders were more responsive to the mating displays of their wolf spider prey when these displays were multimodal, containing both visual and seismic signals (Roberts et al. 2007).

#### The Influence of Interceptive Eavesdropping by Natural Enemies on Signaling Systems

When eavesdropping is beneficial, there may be strong selection on eavesdroppers to be better able to perceive the signals of another species. A classic example of this is the convergent evolution of ears in tachinid and sarcophagid flies to allow them to eavesdrop on the acoustic signals generated by their insect hosts (reviewed in Hedwig and Robert 2014). However, some of the most striking examples of the effects of eavesdropping on the evolution of communication are adaptations that allow species to avoid being eavesdropped upon. In many species whose signals have the potential to be conspicuous to their natural enemies, signalers employ a range of strategies to limit the ability of unwanted receivers to intercept their signals. The evolution of these strategies will be shaped by pressures to maximize attractiveness and localizability to desired conspecific receivers, while minimizing attractiveness and localizability to heterospecific interceptive eavesdroppers. Below are some illustrative examples of a few such strategies.

#### Signaling in a Modality Not Perceived by Potential Eavesdroppers

Prey species may be able to reduce the risk of interceptive eavesdropping by heterospecifics by signaling in modalities in which potential eavesdroppers show reduced, or a lack of, perceptual sensitivity. Mantid shrimp produce intraspecific signals that utilize circularly polarized light (Gagnon et al. 2015); this type of light is exceedingly rare underwater, as are the sensory capabilities capable of detecting it. This suggests it may be a covert signal unavailable to would-be eavesdroppers. In a similar fashion, males of several neotropical katydid species, in which males signal in the understory to attract females, have shifted from signaling

primarily in the acoustic domain to signaling primarily through seismic tremulations, to avoid eavesdropping by acoustically orienting bats (Morris et al. 1994). Unlike acoustic signals, seismic signals are short range and receivers of seismic signals must be in contact with the same signaling substrate to receive signals (Cocroft and Rodríguez 2005), meaning these signals are unavailable to their bat predators.

**Limiting Detectability of Signals by Eavesdroppers** Another means of decreasing the possibility of signals being intercepted by eavesdropping predators, while not necessarily shifting to an undetectable modality, is to employ signaling strategies that increase the difficulty for predators to detect or localize signals. Reducing the active space signals occupy is one means of accomplishing this. In many species of moths, males produce low amplitude ultrasonic signals that are important in female courtship; such “quiet” signals may limit the scope for interception by bats (Nakano et al. 2008). Similarly, neotropical katydids that occupy habitats containing insectivorous bats produce calls with higher ultrasonic carrier frequencies, causing greater environmental attenuation of calls and reducing the range at which eavesdropping bats can hear them (Morris et al. 1994). These same katydids nicely demonstrate another means of reducing the likelihood of eavesdropping, reducing the time spent signaling. Neotropical katydids at risk from bat predation have acoustic calls with lower duty cycles (i.e., there is a greater proportion of silent time per signal period), and males supplement this reduced calling with seismic tremulation signals (Belwood and Morris 1987). Interestingly, increasing duty cycle may also be a means to reduce the risks of eavesdropping as certain auditory systems find localizing near-constant acoustic signals more difficult than intermittent ones (Michelsen 1998).

**Detection of Eavesdroppers and Cessation of Calling** Many signaling species can flexibly respond to the presence of a predator to reduce their risks of capture. The primary response in many species is cessation of signaling when a

potential eavesdropper is detected. Calling toadfish cease calling when they hear echolocation pops made by foraging dolphins (Remage-Healey et al. 2006), and male field crickets cease calling when disturbed (Lewkiewicz and Zuk 2004). The latency for these crickets to resume calling after disturbance is positively correlated with the prevalence of acoustically orienting parasitoid flies in their population (Lewkiewicz and Zuk 2004). Animals may also be attuned to telltale signs of enemy detection by conspecifics. In túngara frogs, males cease calling in response to the abrupt cessation of calling by their neighbors (Dapper et al. 2011), and, in oak treehoppers, maternal signals induce cessation of offspring signaling during attacks by eavesdropping predators (Hamel and Cocroft 2019).

**Signaling at Safer Times or from Safer Places** Prey species can reduce the risks of interception by signaling strategically at certain times or places. The neotropical katydid *Docidocercus gigliotosi* produces a much greater proportion of seismic tremulatory signals (vs. acoustic signals) when the moon is full, and remaining inconspicuous will be more important for reducing the risks from visually hunting predators (Römer et al. 2010). Conversely, the tree frog *Smilisca sila*, which detects bat predators visually, more frequently produces calls that are attractive to bats when there is greater ambient illumination that allows for better predator detection (Tuttle and Ryan 1982). *S. sila* also chooses calling spots with high levels of ambient noise that overlaps the frequency range of their calls, as this makes their calls less attractive to bats (Tuttle and Ryan 1982).

**Shifting Receiver Preferences and Signal Characteristics** Some prey species and eavesdropping predators may be in a co-evolutionary arms race in which prey species continually shift their signals and preferences within a modality to differ from those of predators, while predators try to track these changes. In field cricket populations that have ceased producing ancestral calls due to the recent introduction of

parasitoid flies attracted to these calls, males signal to females with a novel “purr” courtship signal which attracts female crickets but not parasitoids (Tinghitella et al. 2021). Similarly, pine beetles show spatial and temporal variation in their communicative pheromone blends and show enhanced preference for the blend associated with their specific time and locality whereas this is not true for sympatric eavesdropping predators (Raffa et al. 2007). In fact, when comparing communities from Wisconsin and California, predators from each location were more attracted to pine beetle pheromones from the opposite location than to their local population, while pine beetles preferred their local conspecific pheromones (Raffa and Dahlen 1995). This suggests that populations are continually shifting these blends to evade eavesdropping (Raffa et al. 2007). However, a specialist parasitoid showed identical preferences as local conspecific receivers, suggesting this tactic may be effective only at limiting eavesdropping by generalist predators.

**Employing Social Behavior to Mitigate Risks of Eavesdropping** Species may also be able to utilize social strategies to reduce the risks of interceptive eavesdropping. Signaling aggregations occur in many species, and simple dilution effects in which signalers suffer lower per capita risk from predators and parasites could be one benefit. Acoustically signaling male túngara frogs and moths (*Achroia grisella*) experience lower per capita predation risk when calling in leks of increasing size (Alem et al. 2011; Ryan et al. 1981). Additionally, benefits of communal signaling may be enhanced by coordinated signal-timing among chorus-mates. Males of the frog *Smilisca sila* call in near-perfect synchrony, exploiting an auditory illusion in predators and parasites to reduce their attractiveness to these enemies (Leggett et al. 2020). Further, when males call in synchrony, this preserves silent gaps between synchronized calls, which may allow cues of approaching predators to be more effectively detected, allowing appropriate responses to approaching predators (Greenfield 2015).

### Interceptive Eavesdropping on Predator-Alarm Calls

Another form of interceptive eavesdropping that commonly takes place is one species gaining information about the presence of a predator by eavesdropping on the alarm calls of a hetero-specific (the ideas presented in this section are reviewed in Magrath et al. 2015). This can allow individuals of the eavesdropping species to cast the net of predator detection more widely, by increasing the number of individuals that can alert them to a predator's presence. A species may also gain better information about the presence of predators if, for instance, the eavesdropped-upon species has better predator-detection abilities or typically occupies vantage points beneficial for predator detection, e.g., a higher stratum in the canopy. The benefits of eavesdropping will be dependent on the degree to which the complements of predators that pose risks to the signaling and eavesdropping species overlap, with higher overlap allowing greater benefits to eavesdroppers. In principle, this form of eavesdropping could occur via different sensory modalities but has currently been demonstrated primarily in the acoustic modality. This is likely partly due to ease with which acoustic signals can be perceived and studied by researchers, but the rapid, loud, and omnidirectional transmission of acoustic alarm calls may make them broadly suitable for alarm signals, while also making eavesdropping relatively simple for any nearby animal.

This form of eavesdropping poses less obvious costs to signalers than eavesdropping by predators does, if any. Indeed, it may be in a signaler's benefit for heterospecifics to eavesdrop. An increased number of individuals moving to cover upon receiving an alarm call may cause greater commotion, which could confuse a predator to a greater degree (Sherman 1985). Additionally, eavesdropping heterospecifics may be motivated to form mixed-flock species allowing reciprocal eavesdropping to benefit both species. In such a case, mutualistic communication may eventually evolve, causing this to cease to be eavesdropping as individuals from the cooperating species become intended receivers. Eavesdropping by

heterospecifics may also allow opportunities for occasional dishonesty which, if kept under a certain threshold frequency, could allow exploitation of heterospecific resources, as in the case of fork-tailed drongos deceiving meerkats (Flower 2011).

#### Interceptive Eavesdropping to Locate Resources

Eavesdropping by conspecifics has focused on social eavesdropping (see next section), with less of an emphasis on interceptive eavesdropping. However, scenarios exist in which conspecifics may benefit from intercepting signals that offer information on the location of the signaler or the location of a resource that has been discovered by the signaler. Duets occur in many singing insects, in which females call in response to calling males, allowing the calling male to locate that female. Some males adopt a parasitic strategy in which they do not call but will home in on female responses to male callers to mate with them (Otte 1972). For this to be considered eavesdropping, we must assume that the female is directing the signal specifically as a reply to the calling male, rather than this being a generalized signal to all conspecific males within earshot. Interestingly, males of *Caedicia* katydids append a chirp to the ends of their calls, which seems to obscure the female response from rivals, thwarting potential eavesdroppers (Hammond and Bailey 2003). Similarly, signals may cue eavesdroppers into the location of rare ecological resources. Many animals give food calls to attract certain conspecifics to forage, and it is likely that conspecifics (and possibly heterospecifics) could eavesdrop on such calls to pilfer resources from signalers.

#### Social Eavesdropping

As discussed with regard to interceptive eavesdropping, eavesdropping on signals themselves can be informative. However, signals are selected to influence receiver behavior, and receivers are selected to respond in the way that best serves their interest, so additional information not contained within the signals themselves can be gleaned by observing the behavior of interactants within a communicative exchange. This is referred to as social eavesdropping (Peake 2005).

Information stemming from social interactions among conspecifics tends to be more salient to other conspecifics rather than heterospecifics; thus, social eavesdropping tends to be a phenomenon that occurs within species (Peake 2005).

Communicative events such as aggressive contests often involve multiple signals being sent back and forth between interactants, and multiple responses from each interactant to the signals of the other, before a favorable outcome is reached (Hardy and Briffa 2013). Individuals in social species are attentive to interactions among conspecifics (Abril-de-Abreu et al. 2015), and, by observing interactions, social eavesdroppers can glean information about the relationships between communicating individuals and/or make relative comparisons of salient traits of individuals. For example, female crayfish that observed a fight between two males preferentially approached and contacted fight winners, while females who did not witness the fight showed no preference (Aquiloni and Gherardi 2010). This suggests females use information gleaned from the outcome of male combat when choosing mates, rather than simply basing choice on characteristics of the individual males themselves.

The costs or benefits of social eavesdropping are often asymmetrical among interactants. When considering the aforementioned crayfish example, combat winners benefit from an increase in attractiveness to nearby females due to eavesdropping, while the opposite is true for the loser of the exchange (Aquiloni and Gherardi 2010). Such asymmetrical payoffs could lead to different strategies employed by individuals occupying different roles in an interaction. Victory displays are widespread in communication networks and may be a means for a winner of an aggressive exchange to capitalize on the benefits of social eavesdropping by conspecifics (Bower 2005). Conversely, losers may be expected to behave in a way that reduces the likelihood that this information spreads, such as signaling at low amplitude (Dabelsteen et al. 1998). In certain situations, eavesdropping could have similar payoffs for both individuals involved in an interaction. For example, coalition partners could both benefit from conspecifics observing them engage in affiliative

signals, as this will advertise their combined strength to potential challengers.

The benefits of eavesdropping to the eavesdroppers will likely be influenced by the risks or costs that might have to be incurred to gain information about individuals or pairs via direct sampling. For instance, if escalated combat can be highly injurious, observing that an aggressive signal from A elicits a submissive signal from B allows an eavesdropper to avoid risking combat with A if it has already been established that they are a less formidable fighter than B (and are, therefore, much less formidable than A). Additionally, the duration of combat or level of escalation of the exchange might provide information regarding how closely matched these individuals are ( $A > B$  vs.  $A \gg B$ ) (Hardy and Briffa 2013). Similarly, observing affiliative signals between coalition partners C and D may offer information regarding the likely combined reaction that an aggressive behavior directed at either C or D is likely to elicit, without having to directly elicit such a reaction. Social eavesdropping likely provides less accurate information than would direct sampling of individuals or relationships (Earley and Dugatkin 2002) but, due to lower risks and less time spent sampling individuals, it could be beneficial in a variety of situations.

#### Social Eavesdropping and Signaling Modalities

As with interceptive eavesdropping, social eavesdropping has been demonstrated across numerous signaling modalities, though it has most often been demonstrated in the visual and acoustic modalities. Below are some examples of interceptive eavesdropping in different modalities:

- (i) **Acoustic signals:** Female great tits eavesdrop on acoustic exchanges between their mate and other males and were more likely to venture into neighboring territories if their mate lost a vocal exchange (Otter et al. 1999) (see below).
- (ii) **Olfactory signals:** Male golden hamsters make judgments about the relative social salience of other males based on the configuration of overmarking of scent marks (Johnston 2005) (see below).

- (iii) **Visual signals:** Paper wasp queens who observed two other queens fighting were less aggressive toward the queen they had observed to initiate more aggression, and receive less aggression, during the fight (Tibbetts et al. 2020).
- (iv) **Seismic signals:** Social eavesdropping has not been thoroughly studied in species that primarily use seismic signals; however, it has been demonstrated in some treehopper and leafhopper species. In these species, males produce jamming signals which disrupt courtship duets between a female and a rival male, suggesting these male-female duets are recognized via social eavesdropping (Mazzoni et al. 2009).
- (v) **Multimodal signals:** Female crayfish that observed a fight between two males preferentially approached and made contact with fight winners, but only if they had been granted both visual and olfactory access while observing the fight (Aquiloni and Gherardi 2010). Many displays contain multimodal elements (Hebets and Papaj 2005); however, testing multimodal communication and eavesdropping is challenging. Many eavesdropping studies have allowed potential eavesdroppers access to only a single modality or have investigated only a single modality among several that might have been available to eavesdroppers. It is likely that many examples of social eavesdroppers utilizing multimodal communication pathways exist that are yet to be identified.

In interceptive eavesdropping, regardless of the modality of the signal, the information contained in the signal is used in essentially the same way; since the goal is usually to locate the signaler, interceptive eavesdroppers must simply orient themselves to move in the direction of highest signal intensity. In social eavesdropping, however, the interactions that must be parsed may look quite different depending on the signaling modalities used. This means that which signal features are salient to eavesdroppers, and which relationships between features of interactants' signals are important, may differ in different

modalities. To demonstrate how signal modality can influence the form that eavesdropping takes, I will elaborate on two examples of eavesdropping in different modalities: acoustic and olfactory.

A classic example of social eavesdropping is eavesdropping on acoustic exchanges in great tits. Females whose mate had “lost” a vocal exchange with an interactive playback speaker, by singing at a lower rate than the playback stimuli, were subsequently more likely to intrude into neighboring territories, potentially indicating female attempts to initiate extra-pair mating (Otter et al. 1999). The same was not true for mates of males who had “won” against this same intruder. The authors interpret this as evidence that the factor motivating female intrusions to neighboring territories is the perceived lower competitive abilities of their mates *relative* to the playback intruder. Thus, females acted on information that it was only possible to gain via listening to the acoustic interaction between their mate and the playback intruder in real time, their mate’s singing rate relative to that of a perceived challenger.

Male golden hamsters communicate in the olfactory channel via scent marks (Johnston 2005). Olfactory signals such as scent marks remain on surfaces for an extended period after the signal has been sent (or left), meaning signalers are often not present in the vicinity when receivers receive the signal. Upon encountering a scent mark, golden hamsters often scent mark on top of this other male’s scent mark, and this represents a temporally staggered social interaction among these males. In much the same way that interactants are not simultaneously present during communicative exchanges, social eavesdroppers are not present to observe this exchange in real time. However, in golden hamsters, eavesdroppers can extract social information from investigating patterns of scent mark overlap (the following research is all reviewed in Johnston 2005). In a series of experiments, males that had encountered two scent marks that overlapped were subsequently introduced to the isolated scent marks of these males, as well as that of a novel male whose scent they had not encountered previously. Subjects spent the same amount of time investigating the novel male’s scent and the

scent of the male whose scent mark had been on the bottom of the scent mark exchange, while investigating the top-marked male’s scent least. The authors interpreted this as demonstrating that the top male was perceived as more familiar; i.e., his scent had been perceived as more salient and so was remembered more strongly as a more socially salient individual. A similar phenomenon was found when males inspected female marking interactions, and this was true even when more of the bottom-marked individual’s scent was present overall. Thus, it appears to be the spatial arrangement of overlapping scents, rather than scent amount, that causes these differences in signaler salience.

The two examples above highlight how social eavesdropping can look different depending on the characteristics of the modality being employed. In the case of the acoustically signaling great tits, females could listen in real time as the communicative exchange unfolded, and simultaneously compare temporal features of songs, the relative song rates. In contrast, due to the temporal decoupling of signal transmission and reception in scent marking, golden hamsters use spatial cues pertaining to scent mark overlap to extract social information. Thus, signal modality determines which features of interacting signals will be informative to eavesdroppers.

### Social Eavesdropping, Social Structure, and Ecology

The feasibility of social eavesdropping in different modalities will likely be constrained by aspects of a species’ ecology and social structure (Otter and Ratcliffe 2005). An acoustic signaling exchange occurring among co-resident females in a cohesive group of social primates is more likely to be perceived and eavesdropped upon by conspecifics than is a web-borne tremulatory interaction between a male and female of a solitary spider species. A species’ habitat will influence the active space of signals, and this effect will differ across modalities. Species in visually cluttered environments will have fewer opportunities to eavesdrop on short-range visual signals than species occupying more open habitats, possibly leading to eavesdropping on acoustic signals to be

more common than visual. Additionally, characteristics of the habitat can influence aspects of social organization, which can have a knock-on effect on the potential for eavesdropping. Resource abundance in an environment may affect territory size and density which could make it more or less likely that an individual territory-holder, or a prospecting female, is within earshot of multiple conspecifics involved in an acoustic exchange (Otter and Ratcliffe 2005).

## Audience Effects

Audience effects represent another phenomenon that can emerge within communication networks. Many animals alter their signaling behavior depending on whether a receiver, or a specific category of receiver, is within range to receive their signal. For example, many species produce alarm calls more frequently when kin are nearby (Sherman 1977). These situations have often been referred to as audience effects in the literature. However, these examples can also simply be subsumed under the broader notion of flexibility in signaling behavior, and the term “audience” as used in some of these examples is used as a synonym for the term “receiver” (Zuberbühler 2008). This can lead to the concept of audience effects being ill-defined. As such, other researchers have defined audience effects in a more specific way, as changes in a signaler’s signaling behavior toward a receiver due to the presence of additional observers who are not themselves engaged in the interaction (Matos and Schlupp 2005). Similarly to the definition of eavesdropping used in this piece, this definition of audience effects requires that communication happens within a communication network, and it requires conspecific individuals to pay attention to, and gain salient information from, interactions between other conspecifics. Thus, the evolution of audience effects relies on an established tendency for eavesdropping in a population.

## Examples of Audience Effects

Many examples of audience effects are documented in the literature, spanning diverse

taxa. Chimpanzee females produce copulation calls when mating but exhibited an audience effect in which they produce calls less frequently when higher-ranked females are nearby, possibly to avoid receiving competitive aggression from these females (Townsend et al. 2008). In field crickets, males engaged in aggressive behavior directed more aggressive displays toward their rival when a female was present to observe the fight (Tachon et al. 1999). Interestingly, the presence or character of audience effects need not be static and may be influenced by characteristics of the signaling individual or their recent experiences. In Siamese fighting fish, males that had won a previous encounter did not show audience effects when participating in subsequent aggressive exchanges. Conversely, losers of previous encounters reduced their use of gill cover displays while maintaining similar levels of more escalated aggressive behaviors when an audience was present (Matos 2002). This differential effect of an audience may suggest differential payoffs of being observed by audiences for winners and losers and an attempt by losers to mitigate these costs.

## Conclusions

In reality, almost all communication occurs within the context of a communication network. This can exert significant influence on the evolution of the signal production and receiver evaluation, such as facilitating eavesdropping and audience effects. Though not discussed in this piece, communicating within networks can also foster interesting means by which signalers can compete with one another, such as signalers exploiting precedence effects in receiver sensory systems to be perceived at the expense of rivals (Greenfield 2015), and signalers sending jamming signals to disrupt communicative exchanges among conspecifics (Mazzoni et al. 2009). Thus, the connectivity among signalers and receivers within communication networks can have profound effects upon the evolution of communication systems and the behavior of signalers and receivers.

## Comorbidity

Bhabotosh Barman

Department of zoology, Banaras Hindu University, Varanasi, India

## Synonyms

Multimorbidity; Polymorbidity

## Definition

Comorbidity has several definitions, but all are based on a single core concept: the co-occurrence of multiple health problems in an individual. This co-occurring condition includes disease, disorders, and illness (Valderas et al. 2009).

Feinstein define comorbidity as “Any distinct additional entity that has existed or may occur during the clinical course of a patient who has the index disease under study.” (Feinstein 1970).

## Cause of Comorbidity

Comorbidity can occur for a variety of reasons. It may be a chance occurrence or may develop because two disorders have shared or overlapping risk factors (e.g., migraine and epilepsy co-occurred, often as a result of head trauma) (Klein et al. 2004). The possible risk factors are genetic susceptibility, family history, environmental factors (e.g., air pollution), different socio-demographic variables (e.g., age, sex), etc.

## Methods for Measurement of Comorbidity

Some of the valid and reliable methods to measure comorbidity are discussed below:

**Charlson index:** The Charlson index is the most extensively studied comorbidity index. This includes 19 diseases and assigns a weight of 1–6 on the basis of the strength of their association with mortality. So, the Charlson index is the sum of the weight for each comorbid condition and can range from 0 to 33 (Ronald et al. 2001).

**Index of Coexistent Disease (ICED):** This index is particularly useful in those studies where mortality and disability are the outcome of interest. ICED has a two-dimensional structure, measuring both pathophysiologic disease severity and disability (de groot et al. 2003). One dimension discusses about the severity level of 14 diseases and the other one discusses about the severity level of 11 physical and mental disability or impairment. In this index, the patient placed on

a four-point scale for each disease and on a three-point scale for each impairment. Then the peak scores of these two dimensions are summarized into a four-point scale, from 0 to 3.

**Cumulative illness rating scale (CIRS):** CIRS gives the good validity and reliability due to its close resemblance to common clinical practice. It rates 13 conceptually valid body systems (e.g., cardiac, vascular, respiratory) on a five-point severity scale, ranging from “none” to “extremely severe.” (Linn et al. 1968).

**Kaplan index:** This index was specifically constructed to investigate the complication of diabetes. It uses two forms of classification: they are type of comorbidity and the pathophysiologic severity of the present comorbid conditions.

## Consequences of Comorbidity

The comorbidity condition covered a broad spectrum of diseases so, it has multiple consequences. This mainly affects the mortality, quality of life, functional status, treatment strategy, and health care of the patients (Ronald et al. 2001).

## Treatment

Comorbidity is more difficult to treat than an alone disorder. It is mainly treated by medication and behavioral therapy (Weel et al. 2006). Sometimes a single medication benefits multiple problems. There are several ways to treat comorbidity: Integrated (treatment of all disease at the same time), sequential (treatment of diseases one by one), and single diagnosis (treatment of only one disease).

## Background

Our world is full of organisms with remarkable cognitive abilities. For example, the Clark's nutcracker, a bird, is capable of remembering the location of thousands of seeds that it stores for the months of winter and spring (Lanner 1996). Some abilities have long been thought to be uniquely human yet more recently have been discovered in nonhuman species as well. A prominent example is tool use which has by now been observed in a variety of species – from insects to primates (see Shumaker et al. 2011). Plentiful other exciting examples can be found in other chapters of this encyclopedia.

So how do those species achieve such proficiencies and how, why, and when did such abilities evolve? Comparisons of different species, discussed in the light of evolution and ecology, may help us finding answers.

Comparative cognition is the study of similarities and differences in how organisms acquire, store, and act on information (Shettleworth 2010). Cognitive processes vary in complexity but the rankings and definitions of the levels of complexity are constantly evolving.

Studying cognition in animals is challenging as it can be notoriously hard to understand the processes within another species' mind without spoken language. Moreover, drawing conclusions about cognition purely from behavior can be deceptive. However, sophisticated tools to tackle those problems have been developed. In order to understand present procedures in comparative cognition it is important to look at its history and development.

In the nineteenth century, cognitive abilities of animals were mainly discussed on the basis of anecdotal reports. While some were carefully considered and interpreted, there are other examples that seem quite problematic to a critical mind, for example, from George Romanes (1884), who described the following incident: A monkey, who was wounded by a hunter, holds out his blood-covered hand. Romanes' interpretation proposed that it clearly did so to evoke guilt in the hunter.

When the century turned, however, critics grew increasingly skeptical about this method and pointed at its vulnerability to anthropomorphism and over-interpretation. Many called for more objective, quantifiable, and replicable methods (e.g., Morgan 1894) leading to decades of focusing such research purely on behavior while evading cognitive studies.

At that time, two traditional schools of science worked on similar questions without much exchange between each other: Experimental psychology, specifically the field of behaviorism, concentrated on answering questions on human behavior by comparing human learning mechanisms to other animals using strictly controlled laboratory experimentation, while avoiding

cognitive explanations (e.g., B.F. Skinner, Edward Thorndike, John Watson). The center of attention was set on an anthropocentric viewpoint: Can other animals do what humans do? And if so: how?

At roughly the same time, biologists, mainly in the fields of ethology and behavioral ecology, focused on detailed observation of wild animals and very naturalistic experiments (e.g., Konrad Lorenz, Nikolaas Tinbergen, and Karl von Frisch). Their interest was largely to place behavior in an ecological and evolutionary framework rather than to focus on animal-human comparisons, which can be called an ecological approach to behavior.

It took decades for both sciences to appreciate each other's values and to recognize that both approaches can complement each other, more than they contradict. Nevertheless, the tools that both schools developed during this time to investigate *behavior* still set the foundation for modern comparative research in *cognition*.

It is however important to mention that while cognitive research on animals was largely put on halt in the first half of the twentieth century, the study on cognition was not forgotten altogether during that time. Some scientists did indeed investigate cognitive processes – prominent examples include Robert Yerkes, Edward Tolman, and Wolfgang Köhler – although early on with less recognition and great controversy. The impetus for the so-called to “cognitive revolution” however was set by the disciplines of computer sciences (e.g., Turing 1950) and linguistics (e.g., Chomsky 1968). Together with the tools provided by biology and psychology it now seemed possible to draw testable inferences from behavior to cognitive processes. Today cognitive science is a thriving interdisciplinary field including cognitive neuroscience, developmental psychology, ethology, psychology, evolutionary biology, anthropology, neuroanatomy, and others.

So why do we need a comparative approach to cognition? The title of an essay written by the evolutionary biologist Theodosius Dobzhansky (1973) is a now well-known phrase: “Nothing in biology makes sense except in the light of

evolution.” But evolution itself is hard to observe. Luckily however we have a seemingly endless supply of “products” of evolution – a vast number of organisms, we can observe. Researchers of the field of comparative cognition study the similarities and differences of those organisms, compare them in respect to their socio-ecological environments and phylogeny to tackle questions on how, when, why, and under what circumstances cognitive abilities emerged.

## Areas of Cognition

As mentioned earlier, levels of complexity of cognitive processes are under constant debate. It is however helpful to define key areas of cognitive research such as fundamental mechanisms and the domains of physical and social cognition (see Shettleworth 2010).

### Fundamental Mechanisms

Those include processes such as perception, learning, and memory. Fundamental mechanisms can be seen as the backbone or building blocks of many complex cognitive abilities. It is for example crucial to perceive, that is, see/hear/smell, a conspecific, learn something about it (e.g., distinguish it as an individual), and memorize the learned, for processes that might be termed “higher” cognitive abilities such as inferring relationships between others. Nevertheless, it is crucial to distinguish whether a positive result in a task might be due to such “higher” cognitive abilities or whether they can be solved merely through “simpler” processes such as associative learning.

### Physical Cognition

How do organisms find their way around? What do they understand about casual relationships? Why do some species use tools? Do they truly understand how tools work? What understanding do they have about basic physical principles of their world? Do they plan ahead? Such and more questions are investigated in research on physical cognition.

## Social Cognition

Research in the social domain on the other hand focuses on cognitive processes that are applied in a social context. Such as: can animals learn from each other? Can they infer a relationship between others by observation? Do animals have prosocial tendencies or can they cooperate with each other? Can they infer a state of mind to others?

## Hypotheses on Cognitive Evolution

Researchers have developed a great variety of hypotheses to explain the evolution of complex cognition. However, detailed discussions are out of the scope of this entry (but see e.g., Burkart et al. 2016). To provide a basic overview however the following part presents some selected influential hypotheses. While some aim to explain the evolution of cognition in general terms, others concentrate on more specific drivers of cognition.

### Physical Characteristics as Drivers for Cognitive Evolution

Some hypotheses propose that the physical characteristics of some organisms primarily lead to larger brains and therefore evolution of complex cognitive abilities (see Dunbar 1998 for a discussion).

One of those is the epiphenomenal hypothesis, which postulates that a large brain is an unavoidable consequence of a large body, which therefore leads to higher cognitive abilities. Another is the developmental hypothesis, which names maternal metabolic input as the driving factor on brain evolution and advanced cognitive abilities as consequence of such. It suggests that the nutritive value of a mother's food intake determines whether brains evolve to larger sizes and complex cognition. Such hypotheses, however, are considered rather outdated by the majority of the modern researchers. As both, developing and maintaining brains, is very costly and evolutionary theory bases on the balance of costs and benefits, it is "intrinsically unlikely that large brains will evolve merely because they can" (Dunbar 1998). This does not imply that influences such as nutrition are not crucial fundamentals but rather that those

factors act as energetic constraints but not as primary *drivers* of the evolution of cognitive abilities.

### Adaptive Intelligence Hypotheses

Adaptive intelligence hypotheses, on the other hand, state that complex cognitive skills and increased brain size are the *result* of an iterated process of a species adaptation to its socio-ecological environment.

Ecological hypotheses propose that brain size is influenced by ecological conditions and different hypotheses have concentrated on different possible drivers. Some postulate that overall ecological complexity, hence how difficult it is to access appropriate food, to find territories and such, influences the evolution of cognitive skills or that advanced cognitive abilities work as a buffer to be able to readily apply flexibly to environmental changes (cognitive buffer hypothesis; Deaner et al. 2003). Others focus on more specific possible drivers such as increased efficiency through technical elements in foraging behavior (technical intelligence hypothesis; Byrne 1997) or advanced physical problem solving skills in tool-using species (physical cognitive adaptive specialization hypothesis; Teschke et al. 2013).

Alternative or complementary are hypotheses, which attribute advanced cognition to social challenges of a species such as learning from others, recognizing others, interacting with others, manipulating others and so forth, in addition to their ecological environments. Social life is highly complex as other individuals are difficult to predict. Therefore, cognitive abilities presumably have emerged to deal with such sets of challenges (social intelligence hypothesis; Humphrey 1976). Again, the investigation of specific social drivers of evolution yielded a variety of different hypotheses. Most prominent are probably hypotheses that attribute this evolution to factors such as the group complexity of a species, for example, how big and variable the group size of a species is (social complexity hypothesis; Bond et al. 2003), the degrees of complexity of long-term pair bonding (social relationship hypothesis; Emery et al. 2007) or cultural aspects (cultural intelligence hypothesis; Whiten and van Schaik 2007).

The examples given are not mutually exclusive and do not provide a complete picture of the great variety of hypotheses that are postulated. Rather it should provide an idea on how those hypotheses are developed and what they might be.

### Domain-General Versus Domain-Specific Intelligence

Whether there is domain-general or domain-specific intelligence in nonhuman animals is an ongoing and controversial debate in cognitive sciences. In theory domain-specific adaptations may be beneficial if the environment is rather predictable while domain-general intelligence might increase an individual's fitness when confronted with fast-changing environments. However, rather recently it has been proposed that both may be coexisting with some species relying more on one kind while another species might profit to a higher degree from the other (see e.g., Burkart et al. 2016 for a detailed discussion).

### Physical Proxies for Advanced Cognition

Note that, for simplicity, brain size was mentioned to be influential on the occurrence of complex cognitive processes. However, how exactly large brains are linked to increased cognitive abilities is a challenging question to answer. Although there seems to be a correlation between relative brain size (brain/body ratio rather than absolute brain size) and complex cognition, there is ongoing controversy on how fitting it is as a proxy. This

becomes particularly important when different taxa are compared as their morphological attributes (not only the size but also, e.g., the structure of the brain) can be substantially different. Most recent findings propose that absolute neuron count, which can be substantially different in brains of the same size, might be the best morphological proxy for complex cognition we have currently available (Olkowicz et al. 2016).

### Tools of Comparative Research

Although an essential aspect, evolutionary theories constitute only one part of research on comparative cognition. The ethologist Nikolaas Tinbergen (1963) famously proposed that a behavior can only be fully understood by addressing questions on four levels: ontogeny, evolution, causation, and function (see Fig. 1). This also holds true for cognition. For research on tool use for example, this means investigating how this ability (1) develops during the course of an individual's lifetime (ontogeny) (e.g., Does it need social input to occur? Does it only develop in a certain ecological environment?), (2) when it emerged in the phylogeny of this species (evolution) (e.g., Did the ability emerge in two species due to convergent or parallel evolution? In other words: Did it develop one or multiple times and when?), (3) what mechanisms are needed (causation) (e.g., What does one need to understand to use

### Comparative Cognition,

**Fig. 1** Symbolic presentation of Tinbergen's four questions on tool use. Wrenches represent tool use

tools? Which process underlay the ability? What areas of the brain are active during the process?), and (4) what function it might serve to increase fitness (e.g., Does it insure stable food supply? Is the food gained more nutritious?) (Fig. 1).

To address those questions researchers often rely on a combination of experimental and observational approaches. Experimental research focuses on investigating something – here a cognitive ability – by changing one variable of interest while keeping other variables as constant as possible. Typically, this is done by testing species, which are closely related but differ in a specific characteristic (e.g., ecology, social structures, morphology, and physiology) and distantly related species, which are similar in the trait that is investigated.

Such an approach has been integrated, for example, in the studies by Teschke et al. (2011, 2013). To investigate whether tool use was either a driver or product of advanced physical cognition woodpecker finches were compared to small tree finches, both belonging to the Darwin's finches living on the Galapagos Islands. The first has shown to be a habitual tool user while the second is not. Therefore, if tool use is either driving or resulting in higher physical competence, woodpecker finches should outperform small tree finches in physical problem solving tasks. On the other hand, this would imply that distantly related species, which also use tools, should have developed advanced physical cognition as well. To test this, Teschke et al. (2013) conducted the same experiments with tool-using New Caledonian crows (distantly related to the Darwin's finches) and nonhabitual tool using corvids, the carrion crows, who are, again, closely

related to New Caledonian crows and distantly related to Darwin's finches (see Fig. 2).

In the same manner one can test for varying social structures, differences in other aspects of feeding ecology and so forth and should, in the end, be provided with a better picture of the drivers of specific cognitive abilities.

It is however important to note that comparative research is not restricted to the comparison between different species. The influences of, for example, pre-experience, rearing, sex, age, dominance, and personality can also be examined comparatively within a species. Also, some species have great intraspecies variation in socio-ecological environments (e.g., climate or group size), which can have an influence on the occurrence and proficiency of specific cognitive abilities.

Observational research is another important analytical tool for comparative cognition. Not only does it provide insight to experimental research (e.g., why might a certain cognitive ability be of advantage for an individual?) but also allows for more naturalistic investigation. It provides a source for information, inspiration, and ecological validity. For profound research, it is crucial to have a well-founded knowledge of the species at hand, preferably from observations in the wild as well as from laboratory populations.

While both approaches, experimental and observational, have their challenges and merits, both are needed for a rounded understanding of a cognitive ability and complement each other. However, in contemporary research there is no definite line between them, as experiments are often conducted in the field or observational data is collected in laboratory settings.

#### Comparative Cognition,

**Fig. 2** Comparison of physical problems solving abilities in Thraupidae (taxonomic family of Darwin's finches) and Corvidae (Teschke et al. 2011, 2013). Wrenches represent habitual tool use

## Progression and Challenges

### The Stepwise Comparison

As each research facility has a limited amount of species available, comparative research progresses largely in a “stepwise” manner. New methods to investigate certain cognitive abilities are usually proposed alongside a dataset from one or a few species. Those methods are then adopted by other researchers and used to test different species. Over time, the amount of species tested and with it the comparative data grows larger. Through iterated discussions, methodology can be developed into further detail and investigations can thus be improved. Moreover, it is often necessary to alter procedures to fit a particular species’ demands. While a primate might use a hand to grab a tool, it may be physically impossible for a bird to use the same limb. Or while novel objects might trigger an approach in one species due to a pre-existing predisposition, it might cause fear in another or indifference in yet another. While some species might rely heavily on visual information others might be more attentive to smell or show certain reactions only in a specific context. Thus, it is crucial to consider those predispositions – might they be of physical, behavioral or physiological nature – when testing different species. The advantage of this stepwise comparison is that those species-specific demands can be met and taken into account. However, modifying methods must be considered carefully as the comparative value might be lowered.

Some test paradigms are used to test for different cognitive abilities. While this is often a productive development it can also be source of confusion and misguided comparisons especially with changing or ill-defined terminology. Possibly one of the most commonly used benchmark paradigms in physical problem solving is the string-pulling test. More than 163 mammalian, avian, and insect species have been tested in over 208 studies (see Jacobs and Osvath 2015 for a detailed review). The basic idea is to attach a reward, which is out of reach to a string that is accessible to the subject. To get to the reward the string has to be pulled, which brings the reward into reach. This straightforward setup has been

frequently used partly because it is quite easy to conduct, with very little prior training and habituation. Also, it allows for a great variety of modifications and control groups. The strings can be vertical or horizontal, there can be one or multiple, strings can be made nonfunctional (e.g., through a cut), multiple strings can vary in orientation, overlap each other, be of different perceptual characteristics (e.g., color), and so forth. Also, string pulling tests have been used to investigate different mechanisms including means-end understanding, goal directedness, associative learning, functional generalization, insight, and more. This resulted in many different explanations and interpretations for similar findings, while on the other hand similar conclusions have been drawn on different outcomes. While it is desirable to go into more detail and therefore make adjustments, this has resulted in a large dataset that is challenging to compare. The paradigm has been used in at least 50 different variations, each of which brings additional factors that can influence the results and therefore researches have to include those factors in their comparisons.

Another challenge of stepwise comparisons is unpublished data. For different reasons (e.g., difficulty in publishing in respectable journal) results that are “negative” or inconclusive are rarely being published and therefore hard to access for the international research community. This can lead to limited exchange between research facilities who are sometimes facing similar sets of problems. Moreover, the value of “negative” results has often been underestimated. However, there seems to be a change in progress and designated journals are determined to close this knowledge gap.

### Large-Scale Comparisons

Because of challenges discussed above some recent studies used strictly the same methodology while testing a variety of influential factors and species. A recent example is a study by MacLean and collaborators (2014), in which 567 individuals of 36 species have been tested on self-control using two types of tasks. Their performance was then correlated to neurological measures such as absolute and relative brain size and

socio-ecological factors such as group size and feeding ecology. Testing procedures were highly conservative and strictly the same for all species. Although this remarkable effort yielded some informative results there have been justifiable questions raised on comparability. For example, one of the two aforementioned tasks required the test subjects to track the hands of the experimenter to successfully choose the correct location of a reward. Jelbert et al. (2016) found, however, that performance in this task varied with hand tracking training in New Caledonian crows. They therefore argue that the poor accuracy of birds as opposed to mammals in the original study might be due to them having greater difficulties to track human hand movements than, for example, primates. Once they received training they seemed to show as high performances as great apes in this task. In the second task, MacLean and colleagues replaced an opaque, baited cylinder with a transparent one. Whether the subjects took a detour to reach the reward inside or try to access it through the transparent wall of the cylinder was then used as a measure for inhibitory control. Vernouillet et al. (2016) tested Clark's nutcrackers in the same task and found that a learning phase was needed for them to consistently choose the detour. The authors argued that one of the explanations to this result might be that less experience with transparent objects gave some species a disadvantage to solve the task and therefore basic habituation to transparency, hence a baseline criterion, should precede the actual tasks. Those examples highlight the importance of not only taking each species predisposition but also pre-experiences into account.

Additionally, it is crucial to keep a critical mind on which species are used for the comparisons. This is especially true for broad evolutionary hypotheses and discussions. For example, in the large-scale study discussed above one of the comparisons made was that of mammals and birds. However, mammals were represented in a larger total number in general and species of each taxa, which are attributed most complex cognitive skills – such as primates in the mammalian taxa and corvids as well as parrots in the avian taxa – were not represented equally. However, once

more corvids were tested in a succeeding study (Kabadayi et al. 2016) the comparison yielded different results.

Clearly, it is never possible to test a complete set of all species and this naturally remains an issue for interpretations on broader evolutionary theories. However, as long as those limitations are kept in mind data can be discussed accordingly.

In general, one might say the biggest challenge in comparative research is the dilemma between comparable methods and compatibility to all study species as well as conclusions drawn from model species to others.

## Possible Directions

To tackle the abovementioned challenges different approaches have been proposed. The following part aims to give an overview of some selected ideas.

### Emphasis on Baseline Criteria

As discussed above, some problems concerning pre-experience and species predispositions can be limited by applying thoroughly designed baseline criteria such as hand-tracking training or habituation to transparent objects in the abovementioned study. Those provide the possibility – at least to some extent – to determine whether test subjects are equally prepared and acquainted with crucial aspects of a certain task that are not directly related to the ability in focus yet are essential to solve the task correctly.

### Multi-task Batteries

One possible approach to minimize the effects of species predispositions is using large test batteries, which aim to test cognitive domains, hence a broader spectrum of cognitive abilities of a certain category, through a variety of tasks. Therefore, the performance of multiple tasks adds up to the total performance in a cognitive domain, which – if chosen considerably – limits the possible influence of species predisposition or other influential factors in one specific task to the overall outcome.

A prominent example of a large cognitive survey, that includes a variety of primate species, is the

primate cognition test battery (PCTB), which was conducted by Hermann and colleagues in 2007. In 16 different tasks, subjects were tested in both, the physical (space, quantities, and causality) and the social domain (social learning, communication, and theory of mind). Although a test battery is not immune to biases that are more appropriate for some species than others, they are a least more robust to those influences than single tasks.

Likewise, multi-task batteries can also be established for more specific cognitive processes. Test subjects can be presented with a variety of tasks which are all designed to tackle the same question. One example of such a study was conducted by Griffin et al. (2014) to measure influential factors of innovative problem solving when confronted with an extractive foraging task. The apparatus, which was offered to the subjects, was baited with four rewards. Each reward could be retrieved through a different motoric movement. Therefore, influences of task characteristics could be recorded. This again gives a more robust picture of a species repertoire and limitations and species predispositions can be found and interpreted accordingly.

### The Multi-access Approach

Similar to a multi-task battery, a multi-access approach provides a framework, in which species predispositions can be uncovered. The crucial difference however is that only one reward is accessible to retrieve. To obtain it different kinds of strategies can be used. Auersperg et al. (2011) used a Plexiglas box, whose four sides offered

four different ways to access the reward (see Fig. 3). Test subjects were therefore free to choose how to approach this task, for example, which solutions to use, whether to stay with previously rewarding solutions or to use multiple solutions over multiple trials. Additionally, the authors were able to block solutions which were heavily used and observe how willingly different species switched between different strategies. This kind of experimental setup provides a fair chance to approach a problem differently and to explore species-specific strategies. Recently it has been used to compare birds, namely, parrots and corvids (Auersperg et al. 2011), as well as great apes (Auersperg et al. unpublished data). Despite very different demands of those distantly related species – most prominently apparent in their morphology – a comparison that has the same basic methodology but still provides opportunity for different innovative strategies has been made possible.

### Holistic Approaches

Quite commonly, experiments are designed for binary outcome: Does an individual or species solve a task correctly or not? Hence, does it have a specific cognitive ability or not? While this works in a straight forward manner it limits the possibly gained information that can be accessed by experiments. Follow-up questions usually include: Why did they fail? Why did they succeed? Which are the mechanisms used? Some experiments were specifically designed to implement ways to tackle those questions within a task itself. One such example is a study by O'Hara

### Comparative Cognition,

**Fig. 3** Kea, a parrot endemic to New Zealand, manipulating a multi-access box (Auersperg et al. 2011)

and colleagues (2015). Although the main focus of the study was to investigate inference by exclusion, which means whether test subjects could infer logical contingencies to certain stimuli – here pictures on a touch screen computer – by excluding familiar but incorrect choices, the study design made it possible to show alternative strategies used. After establishing the contingencies of two baseline pictures, those stimuli were separately paired with novel pictures in a succeeding manner. Through this procedure strategies such as preferring or avoiding novel pictures can be discovered. Therefore, species predisposition can be unveiled and discussed in the context of ecological relevance. Moreover, underlying mechanisms can be discovered in addition to answering questions on the focus ability.

### Specific Error Patterns

Similarly, specific patterns that occur when errors are made in a specific task can be used as means to detect whether similar binary outcomes are due to similar mechanisms. A variety of species have, for example, been tested on “reversal learning” through a procedure as follows: After successfully discriminating between two stimuli, the reward contingencies of those stimuli are reversed. Now the previously rewarded is unrewarded and vice versa. There are two basic ways to approach such a problem. Either one stays with the correct choice until it is incorrect for the first time (win-stay/loose-shift strategy) or one tries to anticipate when the reversal will happen (e.g., through estimating time that passes or through counting trials). Win-stay/loose-shift results in an incorrect first trial after the reversal while anticipation errors can occur also shortly before (see e.g., Laude et al. 2016). If two species are prone to the same type of error it is more likely that the same mechanisms are used to approach this task. Therefore, the position of error can give us more insight into underlying processes than just the information whether a species can learn something or not.

### Lowering Task Demands

Some authors have argued that some tasks set unnecessarily high demands on test subjects to investigate a particular ability. A classic

benchmark paradigm to investigate causal reasoning is the trap tube task. A reward is placed inside a tube and can be brought into reach by using a tool such as a stick. Through the structure of the tube two ways to access the food are possible. However, there is a trap included on one side of the tube floor. If a test subject uses the stick to push the reward towards the trap the reward is lost. The task is used to test to what degree animals understand surface continuity. Seed et al. (2009) have argued that the use of tools adds unnecessary levels of complexity. Therefore, they conducted an experiment with chimpanzees in which the fingers can be used to guide rewards toward one direction. The question of the task is still the same: Does the test subject avoid the side with the trap? However, through the exclusion of tool use as a requirement they lowered the task demands and therefore the testing paradigm can be transferred to other species – including those without tool using abilities.

### Behavioral Coding Alongside Task Performance

Another approach to gain more detailed information is to pay attention to details of the behavior elicited while solving a task. For example, while the above-mentioned study of Griffin et al. (2014) is largely focused on performance and strategies in four small problem solving tasks, they additionally recorded the latency to approach the tasks, the perseverance, through the amount on beak-to-task contacts, and the motor diversity that was used, through the number of different techniques. Although this approach is quite common, it is an important tool to be explicitly mentioned. Influential factors such as described can serve as bases to compare species with different predispositions on the same tasks.

### Outlook

As discussed, a variety of different approaches and ideas have been proposed to tackle the dilemma between comparability and compatibility. Research on comparative cognition has developed from anecdotal reports to a striving field with ever refining methodology. Hypotheses on the

emergence and drivers of cognition are being tested systematically with a growing amount of research adding to the comparative picture. While it originated mainly from two separated schools, it is now becoming common ground for interdisciplinary research which ranges from neurobiology to philosophy, from artificial intelligence to genetics. Combining theories and methods from a variety of different fields as well as new technical possibilities to examine striking cognitive abilities of others set the stage for exciting times to come!

## Comparative Psychology

Juan-Carlos Gómez

School of Psychology and Neuroscience,  
University of St. Andrews, St. Andrews, UK

## Definitions

Comparative psychology (CP) studies the minds and behavior of different animal species describing and explaining similarities and differences across species from an evolutionary perspective. It is closely related to other disciplines, such as ethology, behavioral ecology, physiological psychology, or evolutionary psychology, with scientists frequently working across the boundaries of any restrictive definition. Ethologists and behavioral ecologists typically focus on the study of natural behavior in natural environments trying to explain how behavioral adaptations relate to environmental challenges and conditions, whereas comparative psychologists typically follow a more experimental approach to investigate behavior and psychological processes in controlled laboratory conditions. This distinction is, however, only relative, as ethologists may also conduct experiments in nature or captivity (e.g., imprinting experiments), and psychologists may rely on naturalistic observation or conduct experiments in the wild. Methodological and theoretical boundaries are fluid and flexible among CP and its allied disciplines.

In Europe comparative psychology is frequently identified with evolutionary psychology. However, in other areas, like USA, the label “evolutionary psychology” refers to a closely related but different discipline that aims to elucidate the functions and adaptations of behavioral and

cognitive traits of modern humans from an evolutionary perspective.

Historically, in Germany a more encompassing conception of comparative psychology was proposed in the early twentieth century, integrating the study of animal mind and behavior (*Tierpsychologie*) with developmental and cross-cultural psychology, as exemplified by Heinz Werner's influential "Comparative psychology of mental development," or K. Kaffka's Handbook of *Vergleichende* [Comparative] Psychology, where animal, child, and cross-cultural studies were included under that umbrella term. The idea behind this approach was to understand the origins of human mental processes from the triple "genetic" perspective of their evolution, their development in individuals, and their cultural development. Comparing similarities and differences alongside this triple axis could provide unique insights into mental phenomena. This amalgamation of disciplines was for some time mirrored by the notion of "Genetic Psychology" in America during the early twentieth century (James M. Baldwin). Although these labels are no longer used in that sense, close and fertile relationships continue to exist today between comparative and developmental psychologists, frequently studying similar topics, using similar tasks and methods in experiments, and with individuals and teams some times conducting both types of research simultaneously or closely interacting (e.g., Mike Tomasello).

### **Roles of Comparative Psychology Within Psychology**

Apart from the direct aim of describing and explaining the behavior and psychological processes of animals in comparison with those of humans, CP is seen as providing some potentially key services to other areas of psychology. For example, it has been presented as potentially allowing the study of simpler versions of complex phenomena (e.g., less complex versions of intelligence and thinking, and psychological processes that are independent of language).

Leaving aside the potentially misleading *scala naturae* assumption that may come with this view, one could argue that CP provides the opportunity of studying potentially different versions of similar phenomena, independently of their relative complexity. For example, in comparative anatomy one can analyze the different structures of hands and forelimbs across species, noting their similarities and differences, to better understand their design and functions, without considering if, for example, the design of an arm compared to a wing is more advanced or complex.

Methodologically, CP can contribute to general psychology nonverbal methods of studying phenomena such as intelligence, memory, or perception, potentially applicable to humans. For examples, in the 1920s, Köhler's tests of practical intelligence for chimpanzees (e.g., tool using tests) were very influential in developmental psychology as a way of testing nonverbal practical intelligence in children. CP, in turn, benefits from advances in other areas of psychology, for example, the looking time methods used with human infants by developmental psychology (see later).

CP in addition offers the possibility of testing hypotheses in animals with experiments that for ethical reasons cannot be conducted with humans. For example, Harry Harlow's studies on the dramatic effects of early maternal deprivation on the social development of rhesus monkeys provided essential empirical evidence to support John Bowlby's theory of attachment and decisively contributed to the development of attachment theory in psychology. This success story had, however, a controversial side, concerning the ethical dimension of research in which experimental manipulations cause deleterious consequences on animals, especially nonhuman primates. The ethics of animal behavioral experimentation, or even observation in captive or wild conditions, are an important, evolving aspect of comparative psychology.

CP can also contribute to theoretical debates about psychological processes, especially nonverbal cognitive processes and so-called implicit cognition in humans (see later).

## Historical Origins and Background

CP started in a systematic way when Darwin and his followers included psychological traits, such as intelligence, consciousness, or emotions as part of the evolutionary process. However, the method of accumulation of systematic naturalistic observation, which Darwin used so fruitfully to inspire and support his evolutionary view of nature, failed to provide acceptable scientific standards in the realm of the evolution of psychological traits. Although Darwin himself provided an excellent example of solid comparative research on the expression of emotions (Darwin 1872), his followers faced serious problems of anthropomorphic interpretation and lack of systematic empirical methodology in the study of the animal mind (e.g., George Romanes). A problem with those early attempts at charting the evolution of mental capacities was the anecdotal nature of the evidence. For example, as pointed out by Morgan, seemingly intelligent actions, in the rare occasions when their history could be traced back, frequently appeared to have emerged slowly by blind trial and error. Using rigorous experimental methods Oskar Pfungst debunked some of the more extraordinary anecdotal claims about animal mental capacities, such as “clever” horses possessing sophisticated arithmetic abilities. Seemingly complex performances (e.g., complex arithmetic calculations) could be the product of very simple associative learning mechanisms. Thus, Pfungst demonstrated that the horse “Clever Hans” had learned to stop hitting the ground with his hoof (his nonverbal way of responding to arithmetic questions) when the human questioners unwittingly braced themselves upon reaching the number corresponding to the correct response, thereby giving the horse a cue to stop. If the questioner did not know the answer, then the horse was wrong (Boakes 1984).

In the first third of the twentieth century, in response to the crisis of introspectionism (i.e., using self-observation as a source of data) in human psychology and its mirror image in animal psychology – introspectionism by analogy, i.e., an assumption that similar behaviors should

correspond to similar mental phenomena as experienced by humans –, behaviorist methods and concepts started to dominate the scene, not only of comparative psychology, but of experimental psychology in general.

Thorndike (1911) published his landmark “Animal Intelligence,” a series of carefully executed and recorded experiments showing that adaptive responses to puzzle boxes were slowly acquired by cats and other animals by trial and error, with no evidence of intelligence or understanding. Shortly afterwards J. Watson argued and exemplified how the notions of classical conditioning developed by Ivan Pavlov with dogs could be extended to humans to explain psychological phenomena like phobias. In his behaviorist manifesto, Watson proposed that psychology should focus exclusively on behavior and use only objective observational and experimental methods. The behaviorists vowed to explain both animal and human behavior through the same associationist learning principles, and indeed behaviorist psychology was dominated by animal studies (rats, pigeons), the assumption being that the laws of learning were the same for animals and humans, and laboratory studies with animals would provide the foundations for understanding human behavior (Boakes 1984).

We could term this “deep comparative psychology,” in that the whole of psychology would appear to have become comparative psychology. Because the basic processes of animal and human behavior were assumed to be the same, experiments with animals would reveal the laws of behavior, including human behavior. However, the apparent ascent of CP with behaviorism was accompanied by the important limitation of just focusing research on associative learning processes and with just a few species: mostly rats and pigeons. A second fundamental limitation was that the assumption of identity between the laws of learning across species somehow emptied the term “comparative” of its primary meaning and intended scientific value. There was little to be learned by *comparing* one species to another, since no essential differences were expected. Laboratory animals were simply an efficient and

useful tool for conducting experiments to uncover universal models of the laws of behavior.

The assumption of absolute psychological continuity across animal species was taken to the extreme by radical behaviorists, epitomized by Skinner's (1957) book *Verbal behaviour*, where he argued that the laws of learning discovered in rats and pigeons were enough to explain even the apparently most distinctive feature of humans – language, a type of behavior that just happens to be verbal. Paradoxically, through Chomsky's influential criticisms (Chomsky 1959), this book came in fact to symbolize the downfall of behaviorism in general psychology and the triumph of the so-called “cognitive revolution” and the more general, interdisciplinary enterprise of cognitive science.

This paradigm change also affected CP, which from the 1960s widened again its horizons to address the study of psychological processes other than learning. This was facilitated by the fact that a number of alternative, more cognitively oriented views had survived during the behaviorist years, and from within behaviorism itself some authors had proposed and provided evidence that undermined the strict behaviorist views.

### **Nonbehaviorist Comparative Psychology Before the 1960s**

In parallel to the behaviorist approach, there were two alternative streams of work relevant for comparative psychology during the first half of the twentieth century. One was of biological origin – ethology, the study of natural animal behavior in the wild from an evolutionary perspective (Lorenz, Tinbergen). Although more focused on the diversity of natural behavior patterns across species and how they could be explained as ecological adaptations, ethology had potential implications for understanding the evolution of psychological processes. For example, Konrad Lorenz proposed that Kant's a priori forms of knowledge should be understood as adaptations generated in the process of evolution, and ethologists provided models of motivational processes.

A second nonbehaviorist stream came from within psychology itself. In response to the crisis of introspectionism in general psychology, a new

school known as *Gestalt* psychology developed in Germany from the 1910s. Gestalt psychologists proposed an alternative scientific approach to perception and thought, one dominated by the notion that perceptual and behavioral configurations (*Gestalten*) were primary psychological structures not reducible to elementary associative analysis – perceptions and actions were more than the sum of their constituent parts. One of the earliest empirical contributions of Gestalt psychology consisted of the study of “insightful” problem solving in chimpanzees.

W. Köhler (1917/1921) questioned Thorndike's conclusion that animals do not show intelligent behavior through a series of experiments and observations with captive chimpanzees in a purpose-built facility of the Prussian Academy of Sciences in the island of Tenerife. He reported that when confronted with practical problems, chimpanzees showed evidence of intelligent, or as it became known, “insightful” behavior, i.e., adaptive actions that did not emerge out of the progressive accumulation of behavioral changes by blind trial and error. For example, when confronted with out of reach pieces of food beyond a bar fence, chimpanzees would spontaneously make use of sticks to retrieve the food; or they would move and try to pile boxes under a piece of food hanging from the ceiling to use them as towers to reach their goal.

Köhler's detailed descriptions of their behavior indicated that chimpanzees produced their solutions in a preadapted way, i.e., their actions were suited to the requirements of the problems without having to go through a slow and gradual process of trial and error. Sometimes, these good solutions appeared suddenly, after unsuccessful attempts of a different nature. Interestingly, Köhler based his argument in favor of animal intelligence not only on the successful problem solving actions of the apes, but also on their systematic mistakes. For example, some chimpanzees would try to climb upon a box, that in itself was too short to reach a target, while pressing it tightly up against a wall, as if they expected that the box would stick to the wall. On the one hand, this mistake reveals a lack of understanding of the laws of balance and support, but on the other it reveals an understanding

of the problem – the need to shorten the distance between the support box and the goal. Crucially, a mistake like this could not be explained by trial and error learning, as it cannot possibly have previously worked. It appears to reflect a partially insightful strategy generated by an incomplete “understanding” of the situation.

Köhler’s proposal of insight in chimpanzees came to co-exist with behaviorist approaches in an uneasy relationship over subsequent years. Insight was seen as a challenge to the principles of behaviorism, with good reason as it was grounded on a different, “cognitive” *avant la lettre*, view of psychology in general and comparative psychology in particular.

Behaviorist psychologists tried to explain away insight as the product of associative learning (e.g., maybe Köhler’s chimpanzees, being wild caught, had already acquired their tool using responses in the wild, and in captivity they merely generalized them to similar situations; or maybe these were based on instinctive behaviors) (Boakes 1984). The notion of insight, however, survived these criticisms and controversies, and it is still used and debated in contemporary comparative psychology (Shettleworth 2012).

One reason for its continued appeal is that the notion of insight captures a fundamental challenge for any comparative psychology – the notion of intelligence and understanding without language or explicit reasoning. One of the key potential contributions of comparative psychology to general psychology is indeed to understand forms of intelligence and cognition that are independent of language and explicit conscious experience (Gómez et al. 2017).

From within behaviorism itself, there were discordant voices calling for a CP that was more open to the role of internal processes and variables in explaining behavior. For example, E. Tolman proposed notions of mental map and latent learning based on solid empirical findings demonstrating that rats could learn to navigate mazes in the absence of differential reinforcement. In addition, in the 1960s findings on the quick learning of aversion responses to food demonstrated the role of biological preparedness for certain types of learning of special adaptive significance,

questioning the assumption of absolute equivalence across species: the laws of learning were constrained by ecological conditions and adaptations (Boakes 1984).

The existence of these alternative approaches in the shadow of behaviorism facilitated the transition of CP into the new cognitive approach of psychology and allied disciplines in the 1960–1970s. Comparative psychology turned again to studying, not only behavior, but also the mental processes and mechanisms underlying it. Intelligence, consciousness, memory, intentions, imitation, social learning, problem solving, etc., became targets of comparative research, with the benefit of the rigorous methodological and experimental approaches instilled into psychology during the behaviorist era. Behavioral and cognitive differences across species became again a central target of inquiry, and crucially the evolutionary framework took again central stage to make sense of such differences in CP. Some of the old methodological and conceptual debates (e.g., the tension between observable behavior and inferred cognitive processes, the contraposition of simple learning mechanisms and complex cognition and reasoning) re-emerged within the new framework and are part of contemporary CP.

## Practical Intelligence: Objects and Tool Use

An example of the new directions taken by CP in the 1960s–1970s was the application of Piagetian theory, originally developed to describe and explain human child development, to animal cognition – an example of interaction between developmental and comparative psychology. Piagetian theory proposed a constructivist solution to the traditional nature/nurture and associationist/cognitive debates in psychology, holding that behavioral and cognitive capacities were “constructed” during ontogeny in a dynamic epigenetic interaction between the organisms’ preexisting cognitive capacities and environmental challenges.

Piaget (1936) described cognitive development in human children as a succession of stages leading from innate reflexes to symbolic and

logical (operational) intelligence. Interestingly for comparative psychologists, the very first stage of development – sensorimotor; 0–2 years of age – corresponds to a nonverbal, perception/action dominated type of intelligence that Piaget thought could integrate into a single model behaviorist notions of associative learning and *Gestalt* notions of insight, with each mechanism corresponding to a different developmental substage. Piaget viewed sensorimotor development as a postnatal continuation of embryological development, and intelligence as an adaptation that was in continuity with, and a prolongation of, biological adaptations. This made his theory particularly attractive to comparative psychologists, even if he himself conducted no comparative studies, and only a few of his followers and disciples ever did so (Parker and Gibson 1990).

### Object Permanence

An example of Piagetian influence on CP is the capacity known as object permanence – the ability to track and find objects when they move from one location to another. Piaget described in detail the emergence of this ability in human infants and suggested that it reflected the progressive development of a fundamental cognitive adaptation – conceiving objects as independent entities that continue to exist in the world when one is not perceiving them.

When the Piagetian tasks defining each stage of object permanence were applied to nonhumans, they worked very well, especially, but not exclusively, for primates (a genus with prehensile hands adapted to the manipulation of the environment). Even such particular developmental phenomena as the transitory A-not-B error (the mistake of trying to find an object in the place where it was first hidden, despite seeing that in successive trials it is hidden elsewhere) have been reported for all primate species tested, suggesting that object understanding follows a systematic sequence of development in primates. However, comparative research shows that this overall similarity is accompanied by differences: for example, monkey species tend to pass through stages of object permanence at an accelerated rate (four times faster) than humans and maybe fail to reach the

final stage (invisible displacements). Apes, in contrast, develop only slightly faster than humans and do reach the final stage of invisible displacement (Gómez 2004).

Moreover, when object permanence skills are compared with other sensorimotor abilities, such as locomotion and tool use, a pattern of *heterochrony* emerges. Whereas monkeys and apes display independent locomotion months earlier than humans, they are slower to develop tool using skills, if at all. Different primate species offer different versions of how sensorimotor systems dominated by manipulative skills can be organized. Still other nonprimate species may offer very different versions of sensorimotor systems of action. This is a fine example of comparative research where both similarities and differences are highlighted in an evolutionary framework.

Inevitably, whenever a stage-based theory of development is used, there is a temptation to take a *scala naturae* approach, where the higher levels of intelligence are expected to appear in the closest evolutionary relatives of humans. For example, it was initially reported that the most complex level of object permanence – the ability to track the invisible displacement of objects – was only found in great apes and humans, with potentially positive results in monkey species subject to alternative interpretations. This could mean that invisible displacement understanding might require some sophisticated level of symbolic representation only found in humans and their closest relatives. However, subsequent research has found evidence of invisible displacement understanding in some avian species. Although the exact equivalence of performances and underlying cognitive and neural mechanisms is still under scrutiny and discussion, comparative psychologists have become aware of the power of convergent evolution in shaping the cognitive skills of different species.

### Object Individuation

In the 1990s, developmental psychology moved beyond Piagetian theory. New nonverbal paradigms to study infant cognition emerged requiring minimal amounts of manipulative skill and

suggesting that infant cognition could be more complex than previously thought. For example, by using looking time methods, building on the fact that infants pay longer visual attention to unexpected events, human infants revealed some understanding of object permanence before being able to correctly respond in Piagetian object search tasks (Gómez 2004). These new methods allowed the investigation of other aspects of cognition in infants, and soon they were imported into CP.

An example is the study of *object individuation*, i.e., the ability to identify and keep track of objects or infer their whereabouts on the basis of their individual identity. For example, I may have two identical apples, but know that one is in my pocket and the other on the table. They look the same, but I know and track them as different objects on the basis of their different spatiotemporal relations. Conversely, I may see that you put an apple and a banana in your bag. Although they share the approximate same location at the same time, I know they are two different objects because I individuate them on the basis of their appearance.

This problem was first studied in human babies using looking time methods with the unexpected result that at 10 months of age babies could individuate objects only using spatiotemporal information, but not featural information. For example, if babies saw a toy duck coming from behind a screen, and then, after the duck returned behind the screen, they saw a ball coming from behind the same screen and then returning, when the screen was lowered, they were not “surprised” (did not look longer) if, due to an experimental trick, only one of the objects was there, as if they had been assuming, in their representational record of what lies behind the screen, that the duck and the ball were one and the same object.

This led some developmentalists to suggest the hypothesis that so-called “featural object individuation” might be linked to language acquisition and appear only as human infants start to acquire their first naming abilities in their second year of life, as if using labels to identify objects prompted and supported their ability to individuate objects by their features (Xu 1999).

This called for comparative research: if this hypothesis was correct, then nonhuman primates should not be capable of featural/property individuation. However, several species of apes and monkeys have demonstrated that they do possess this ability. For example, in one test primates see one piece of banana dropped into a box. This is a trick box, since unbeknownst to them, the piece of banana remains in a trap never reaching the bottom, which is the only part of the box they have access to. When they try to retrieve the banana, if instead they find a piece of, say, apple (surreptitiously placed there by the experimenters), they tend to continue searching in the box more frequently than if they do find a piece of banana. This suggests that they have the ability to individuate objects by their appearance, and not just their spatiotemporal parameters, and therefore featural object individuation is not exclusively human and dependent upon language, but an evolutionarily older trait of primate cognition (Cacchione et al. 2016).

Attempts have been made to trace back the origins of this ability to nonprimate species, with mixed and still controversial results (see Fontanari et al. 2011, for a study with newly hatched chickens).

## Convergent Evolution and the Challenge of Operationalization

Historically, CP has tended to be biased by a tacit *scala naturae* attitude, that is, an assumption that the species evolutionarily closer to humans, such as primates, and among primates great apes, would show higher levels of intelligence and more complex behaviors. For example, tool use was hailed as an indication of complex intelligence in apes, whereas reports of tool use in distant species such as birds tended to be dismissed as instances of inflexible, “instinctive” like behaviors. In the last years, this attitude has changed. Evidence has mounted that nonprimate species display complex behaviors that may reflect flexible cognitive processes emerged by convergent evolution and in differently designed brains. The importance of relative brain size as a potential index of cognitive

sophistication has been questioned with proposals that other factors like neural connectivity and number of neurons may be more relevant and help understand why small brains could generate cognitive and behavioral complexity (Emery 2004; Gunturkun and Bugnyard 2016).

One of the most surprising sources of potential complex cognition in very small brains comes from insects. For example, bumblebees have demonstrated an ability to learn to solve simple “string problems” (pulling an artificial flower stem to slide it from underneath a glass and thereby gain access to pollen) and to display flexible observational learning of a basic manipulative skill (Loukola et al. 2017). One interpretation is that such findings of complex behavior in species so distant to humans and primates should be interpreted as evidence of the power of convergent evolution in producing and implementing complex cognition in very different brains. Some authors, however, propose that complex behaviors may not always require complex cognitive mechanisms, and such examples reveal that even in humans and primates in general we may overestimate the role of cognition in producing complex adaptive behavior (Shettleworth 2010).

### The Challenge of Operationalization

When probing the cognitive and motivational processes of nonverbal organisms, comparative psychologists are faced with the problem of establishing objective behavioral criteria that are proof of their existence. For example, to determine if an animal is capable of intentional, goal-directed action, we need criteria that distinguish this from other types of action (e.g., associative learning). This problem is largely shared with developmental psychologists, especially those studying early infancy. This is frequently known as the problem of “operationalization.” For the problem of intentional action, criteria typically include persistence until a goal is reached, variation in means deployed, cessation when the goal is attained, etc. For the problem of intentional communication, to the above additional criteria are added, for example, directedness to an agent, eye contact, pause to allow for a response (Townsend et al. 2016).

A problem with operationalizations is that they might appear to fail to do the job of distinguishing between different cognitive processes when their application leads to attributing complex cognitive, human-like processes to species that are very distant from humans and are traditionally not perceived as cognitively sophisticated. For example, Vail et al. (2013) applied the criteria of communicative intentionality to fish signaling behavior in collaborative hunting finding that they might qualify as instances of intentional communication. Some insect behaviors frequently appear to fulfill criteria of complex cognition at least in some limited, specialized areas. For example, one species of ants displays helping behavior to conspecifics when these are stuck in a way that could fulfill at least some of the criteria for empathic targeted help (Taylor et al. 2013).

When this happens, comparative psychologists are faced with a dilemma. They can either attribute to the species concerned the complex processes supposedly captured by the operationalized criteria, or decide to revise the criteria as being incomplete and imprecise. One problem is that this may lead to a “moving the goal post” effect, i.e., changing criteria to make them fit preconceived conclusions about which species possess certain cognitive processes. On the other hand, empirically informed and theoretically motivated refinements are necessary to advance our understanding of the structure and function of mental processes. An important part of this may consist of finding the correct positioning of operational “goal posts,” through evidence-based and conceptually justified recalibration of behavioral criteria.

### Domestication, Captivity, and Development

One species evolutionarily distant to humans that has provided a wealth of unexpected comparative findings in the last years is the dog. Dogs pass social cognitive tests that primates, including apes, find difficult. For example, in the object choice test (where subjects are prompted to choose a container with food by a human who

gestures or looks at the correct location), dogs have demonstrated a high degree of sensitivity to human referential signals, such as pointing gestures and deictic gaze, whereas apes find it difficult to make use of these communicative signals to find the hidden food, even if they can correctly interpret noncommunicative signals such as reaching (Hare and Tomasello 2004). One interpretation is that during the process of dog domestication humans artificially selected animals who were better able to respond to typical human communicative cues, whereas apes have to rely upon their own communicative abilities, or an exaptation thereof, which might be insufficient to pass such tests. One open question is to what extent the underlying cognitive and motivational processes selected in dogs are similar to those operating in human infants, or completely different mechanisms mimicking typical human responses.

Closely related to the effects of evolutionary domestication on cognition is the issue of how “domestic” rearing by humans may affect the cognitive and behavioral phenotype of wild animals reared in captivity, especially apes and monkeys, whose attachment patterns make them especially suitable for human rearing.

### **Ape in the House Studies**

From very early, comparative psychologists were tempted by cross fostering experiments where infant apes were reared by humans to test how human-like ape behavior and cognition can become when reared in human conditions. Classic studies include Kellogg and Kellogg and Ladygina-Kohts, where it was found that despite profound similarities in some aspects of development (e.g., emotional expression, tool use) and ape malleability and responsiveness to human rearing, apes decisively diverged from older child development, most crucially with the acquisition of language, which remained completely absent in domestic apes. Hayes and Hayes’ systematic and deliberate attempt at teaching speech to a chimpanzee definitively showed the futility of the attempt (Boakes 1984).

A controversial variety of this ape in the house experiment became particularly popular during the 1960s and 1970s in the so-called “linguistic

apes” experiments. In these, infant apes were systematically and intensively trained to acquire non-speech linguistic skills with a variety of procedures, ranging from computer based, artificially designed “lexigram” languages, to the use of a version of deaf signed languages to take advantage of the apes manual dexterity. Although initial reports suggested an unprecedented degree of success (with some apes acquiring several hundred “words” and combining them into rudimentary “sentences”), the results of the studies were questioned and remain controversial, both in terms of what was demonstrated about the apes’ ability to acquire linguistic skills and in terms of the ethical implications of such intrusive, largely irreversible manipulation of the lives of the participant apes (Gómez 2004).

In the best known critical study, Terrace and collaborators concluded that their chimpanzee’s acquisitions in signed language did not show evidence of grammatical organization and probably not even symbolic value and could be best described as a combination of acquired conditioned responses and copycat signing based on the signs and cues provided by his keepers. They suggested that this negative conclusion should be made extensive to all the linguistic ape studies. However, other research teams disputed this interpretation and the comparability of the conditions under which Terrace’s chimpanzee was reared and trained to their own, according to them, better conceived and executed attempts. Thus, Savage-Rumbaugh presented results that, according to her and her collaborators, suggested linguistic skills in bonobos (Savage-Rumbaugh et al. 1993).

Ape in the house studies, including language teaching experiments, have left an uncertain legacy, fraught with ethical misgivings and equivocal data and interpretations.

### **Captivity, Behavior, and Cognition**

Beyond the controversial human rearing studies, a substantial part of the findings of comparative psychology come from captive animals, in zoos, research stations, or laboratories. A potential objection to studies with captive animals is that results may lack ecological validity, i.e., that they may not reflect the “true” abilities the animals

were evolutionarily selected for, but some artifactual or atypical versions of them. However, on the other hand, it can be argued that captivity, when conditions are not impoverished and basic ecological needs of the species are taken care of, may offer especially informative insights into the plasticity and adaptability of animals in response to environmental change – a basic evolutionary process. Few studies have attempted to address explicitly the issue of how captive conditions may affect behavior and cognition from this evolutionary/developmental point of view.

An example is the study of spontaneous gestural communication in apes. Captive apes are capable of developing flexible, intentional (i.e., fulfilling operationalized criteria of communicative intentionality; see above) pointing gestures that they use to interact with humans (but rarely among themselves). These gestures are rarely observed in the wild, but typically become a standard component of the captive ape repertoire to interact with humans. Pointing gestures are a universal form of human communication, although it remains disputed to what extent they are a biological adaptation or a highly constrained behavior pattern subject to some morphological variation across cultures. The fact that they rarely appear in wild apes, or are rarely used among captive apes for intraspecific communication, opens up a number of interesting questions about the interaction between phylogenetic and ontogenetic factors in the emergence of adaptive behavior patterns (Gómez 2007).

### Enculturated Apes

It has also been suggested that apes reared in close interaction with humans might develop more complex cognition, by becoming “enculturated.” This idea is related to the Russian psychologist Lev Vygotsky’s theory about the mechanisms of human cognitive development. According to him, the natural cognitive abilities of humans are amplified through the process of sociocultural interaction and education that mediates human ontogeny, including learning to use linguistic and other symbols as cognitive tools. Tomasello and Call proposed that “enculturated” apes might be more proficient in certain tasks such as

imitation or understanding intentions, although they later qualified their claims in view of evidence demonstrating that some of these abilities could also be found in nonenculturated apes, and maybe the performance differences could point more to quantitative than qualitative differences in capacity, or be due to the superior familiarity of apes experienced with humans in solving human inspired tasks. The issue of the role of human influence on the behavioral and cognitive phenotypes of other animal species remains open (Gómez 2004).

### Experiments in the Wild: The Meanings of Animal Signals

One of the topics addressed by CP in a new way after the cognitive revolution was the nature of animal communication. Previously, animals’ signals had been assumed to be essentially different to human language – inflexible emotional responses without semantic meaning or intentionality. The linguistic ape experiments discussed above tried to uncover latent capacities for more sophisticated communication through direct training. A second approach tried to reassess the natural communicative behavior of animals through the innovative use of playback experiments in the wild and in captivity.

The logic of the playback paradigm is as follows. To know what a signal “means” to an animal, a prerecorded vocalization is played when the referent (or triggering event) of the vocalization is not present, and the reaction of the animals is observed. If they react as they would in the presence of the referent, the conclusion is that the signal “means” that referent for them. For example, Cheney and Seyfarth played recordings of alarm calls given by vervet monkeys to different predators. They found that the monkeys reacted with appropriate escape responses and even seemed to engage in visual search of the predator in the appropriate direction (e.g., the sky for an eagle alarm, or the ground for a snake alarm). This led them to claim that alarm vocalizations in monkeys might work as some sort of primitive “words” with specific meanings.

Subsequent research using variants of the playback paradigm found this phenomenon in many other primate and nonprimate species. Variants of the playback technique have been used to investigate more complex aspects of vocal communication, for example, the possibility of rudimentary syntactic combinations whereby signal combinations might change the meanings of calls (Zuberbuehler 2010).

At a theoretical level, there continues to be disagreement about what is the correct interpretation of these findings. Do the different vocalizations simply work as emotional signals without referents in a more sophisticated way than previously thought? Are they reflex or learned reactions without complex semantic representations? Or do they constitute evolutionary precursors of some basic aspects of language? (Fischer 2011).

### Intentional Gestures in Communication

An alternative cognitive approach to animal communication (and the enduring problem of language evolution) studies if other animals can engage in intentional gestural communication. Humans not only mean things with words, but also with gestures, for example, pointing gestures. While some authors were busy trying to teach language to apes, others studied their spontaneous communication with humans in captivity, reporting that they developed a repertoire of gestures both similar and different to those used by prelinguistic human children. For example, they use a whole hand version of index finger pointing (although under physical constraints like having to point through a narrow whole, they choose index finger pointing). Importantly, these gestures seem to be accompanied by joint attention behaviors (gaze following and eye contact), which in human infants is considered to be an index of communicative intent. Systematic studies of intraspecific gestural communication in the wild report complex gestural repertoires with a variety of meanings (Byrne et al. 2017). There is debate about the extent to which the underlying joint attention processes and meaning in apes and other animals' gestural communication are similar to humans, or humans display a special type of joint attention adapted to cooperative interaction

and the exchange of information. For example, apes tend to use their gestures to make requests and regulate others behavior, whereas human infants in addition make extensive use of so called protodeclarative gestures (to show things to others) (Gómez 2004).

In sum, studies of intraspecific gestural communication in apes in captivity and the wild have explored the flexibility and intentionality of their gestural repertoire. However, there remains controversy as to how the underlying cognitive and motivational processes in the communication of nonhumans compare to those of humans, including prelinguistic human infants.

### Comparative Psychology and Cognitive Science: Theory of Mind

Theory of mind (ToM), defined as the ability to adaptively react to and represent the mental states (intentions, desires, beliefs) of other organisms, has been an extremely productive area of interdisciplinary research over the last decades, involving general psychology, neuroscience, psychopathology, and philosophy, among other disciplines. The whole area was kickstarted by comparative psychology and has remained one of its most active, interdisciplinary, and influential areas of research.

Premack and Woodruff conducted an ingenious study with an original take on the classical tool-using tasks of Köhler (1921) – instead of humans observing if chimpanzees can solve problems, a chimpanzee watched a human confronted with a problem (e.g., trying to reach a bunch of bananas hanging from the ceiling). The chimpanzee – a “linguistically” trained ape, used to this type of experimental procedure – then chose one of two photographs – one depicting the correct solution (e.g., a human climbing on a box to be able to reach the bananas), the other showing an irrelevant action. The chimpanzee was able to select the correct option, thereby demonstrating “problem solving comprehension,” i.e., some understanding of what it is for others to confront and solve a problem.

Premack and Woodruff (1978) suggested that this problem solving understanding must involve

an ability to attribute mental states to other agents: understanding their intentions, desires and beliefs, or, as they termed it, having a “Theory of mind.” The chimpanzee – they suggested – had to perceive the keeper’s observable behavior – stretching the arm in the direction of the bananas – as caused by an unobservable *intention* to get them. Because to predict and explain behavior, mental states must be inferred as unobservable causes, the authors coined the term “Theory of mind” to refer to this ability. This theoretical paper was commented upon by other psychologists, ethologists, philosophers, and cognitive scientists. They came to the conclusion that the evidence presented by Premack and Woodruff for chimpanzee ToM was weak, but the question was an excellent one, and not only for chimpanzees, but for humans as well, but in need of detailed empirical exploration.

It was agreed that the best way to test if an organism has a theory of mind (ToM) was to create a situation where one has to predict the behavior of another organism that has an erroneous representation (a false belief) of reality. For example, predicting that an organism that believes that there is food in box A, when in fact the food is in box B, will nonetheless look for it in the empty box A. Unfortunately, comparative psychologists were initially unable to develop a test like this for chimpanzees or other animals. It was developmental psychologists that first reaped the benefits of the ToM debate, establishing that the landmark of false belief understanding emerges in children only at around 4 years of age, but this is preceded by the ability to understand other mental states: perceptual states like seeing at around 1 year, desires at around 2 years, and knowledge and ignorance at around 3 years (Baillargeon and Bian 2016).

The findings of developmental psychologists inspired back comparative psychologists who reported spontaneous behaviors in animals, especially primates, that might reveal some of those ToM abilities. For example, Whiten and Byrne (1988) compiled observations of tactical deception among nonhuman primates suggesting an ability to conceal things from others’ sight or even some potential examples of trying to create

false beliefs in others,. These might be evidence of ToM skills in nonhumans. This gave rise to the “Machiavellian Intelligence” hypothesis – the idea that the challenges of navigating the complexities of the social world (predicting and manipulating conspecifics’ behavior) might have been a key determinant in the evolution of intelligence, with theory of mind abilities (also known as “mindreading” or “natural theories of mind”) as a key adaptive component.

However, initial attempts to apply experimental methodology to test this suggestive evidence produced mostly negative results. A comprehensive series of experiments with chimpanzees found that they could not understand even the simplest of mental states: visual perception (Povinelli and Eddy 1996), as they did not discriminate between humans who could and could not possibly see their begging gestures (e.g., human oriented to the front with her eyes open versus human looking sideways). By the end of the 1990s, it looked as if the answer to the question posed by Premack and Woodruff was negative – chimpanzees and non-human primates in general do not have a ToM ability, which might be an exclusively human cognitive skill.

This changed shortly afterwards when Hare et al. (2000, 2001) introduced a new experimental paradigm inspired by the idea that we should not be testing chimpanzees’ theories of the human mind (as in the cooperative requesting tasks used before), but chimpanzees theories of chimpanzee minds. They devised a competitive task, based on the fact that in their natural behavior chimpanzees rarely share food, but rather compete for it, with dominant chimpanzees typically gaining access to disputed food.

They found that subordinate chimpanzees, when given a slight head start in a competitive situation, preferentially targeted food that was visible only to them over food that was also visible to a dominant individual. They were even able to take into account if a piece of food currently invisible to a dominant had been previously seen by him being placed in that location. The conclusion was that, when properly tested with a paradigm that takes into account the motives and typical behaviors of the species in natural

conditions, chimpanzees did show evidence of understanding at least some mental states like seeing and knowledge.

However, as so frequently happens in comparative psychology, critics argued that even these ingenious new experiments could not completely rule out the possibility of finding more parsimonious explanations of the animals' behavior, such as using simple behavioral associations or behavioral rules. This is an example of the traditional debate between rich and lean interpretations of animal behavior, in which critics provide reductionist re-interpretations of new pieces of experimental evidence (see problem of operationalization).

Indeed some critics (Penn et al. 2008) even proposed that it might in principle be impossible to prove beyond reasonable doubt that a nonverbal organism has a theory of mind, as it might be logically impossible to disentangle the problem of whether animals are responding to behavioral cues or to representations of the mental states reflected in the cues. The rationale is that to infer a mental state you need to detect some behavioral evidence (e.g., to infer that agent A knows that an apple was placed in location X, you need to see if the agent is present and oriented to the scene.) An observer could learn an association between being present and physically oriented and subsequently being able to find the object without representing that the reason why this happens is that by being present the agent has acquired a representation (knowledge) of the whereabouts of the object. Mentalistic understanding would be "implicit" in that behavioral procedure, but not really in the mind of the organism.

This has generated a complex debate on the nature of mentalistic explanation, the methodological limitations of research with nonverbal organisms, and the nature of implicit knowledge. This debate has recently been exported into developmental psychology to question findings suggesting an early competence to understand false belief in 1- to 2-year-old human infants – traditionally considered to emerge only at around 4 years of age – when tested with looking time methods (Baillargeon and Bian 2016).

Perner (2010) suggested that the behavior reading objection of Povinelli and collaborators is fully

applicable to the infant looking time studies. Only responses where organisms can give explicit evidence of their representations (e.g., by providing a verbal explanation) could be considered as convincing evidence of ToM. This could be seen as an overdue redress of what sometimes is perceived as double standards of scientists studying humans and animals, with rich interpretations being always more easily accepted for humans than animals. However, it also raises a problem of a philosophical nature – whether knowledge should be required to be explicit for it to count as genuine knowledge (see section on Nonverbal Thought and Implicit Knowledge).

In a further instantiation of cross-fertilization, comparative psychologists have recently imported the nonverbal false belief testing methods used with human infants to animals (Krupenye et al. 2016), with positive results for apes, suggesting that "implicit FB understanding" (whether genuinely mentalistic or not) might be shared by all great apes.

In sum, the area of Theory of mind is an excellent example of the potential of CP to interact with other disciplines and provide the sort of scientific value inherent to the comparative method. Comparative psychology has played and continues to play a fundamental role in the debate about the differences between implicit and explicit systems of knowledge, of which the area of theory of mind is but an example.

## Nonverbal Thought and Implicit Knowledge

One of the key contributions of CP to general psychology and cognitive science is to contribute to the understanding of nonverbal intelligence and thought and so-called implicit cognition. In CP there has always been a tension between researchers that try to resolve the problem of thought processes in animals by concentrating on behavior and trying to reduce mental mechanisms to associative processes, and researchers that try to find in animal behavior evidence of nonverbal or implicit cognitive processes that might help understand the origins of human cognition (Gómez et al. 2017).

The challenge of implicit, nonverbal thought is conceptual and methodological. Conceptually, it requires defining forms of thought and intelligence that work without explicit, verbally mediated or verbally expressed reasoning. Methodologically, it requires finding methods for probing and demonstrating such intelligent mechanisms in animals who cannot report about the way in which they see and approach problems. The close relation between comparative and developmental psychology examined in other sections of this entry is due to sharing both challenges (in the case of the latter only to a certain extent, since children eventually develop linguistic skills).

The challenge of nonverbal or implicit thought is not exclusive to CP. There is ample evidence that human adults engage in mental processes that are not verbally reportable: so-called “implicit cognition” is pervasive in humans, and it is uncovered through indirect, nonverbal methods and experiments. However, in general psychology and cognitive science nobody has been able to provide so far an accepted definition or characterization of implicit thought. Indeed the most important, unresolved challenge of implicit knowledge is the conceptual one – understanding its very nature. Despite the pervasive use of this notion, not only in psychology, but across many other disciplines, there is no accepted definition or model of what this intuitive notion is. Comparative psychologists are in an ideal position to contribute to solve this conceptual puzzle as they are studying animal minds, which are quintessentially nonverbal (Gómez et al. 2017).

## Conclusion

Over its long history CP has become a discipline with intense and dynamic cross-disciplinary connections (biology, philosophy, cognitive science, neuroscience) at the forefront of research on behavioral and mental processes in an evolutionary framework. Its most unique contribution is the insights provided by comparing different evolutionary and developmental versions of adaptive

systems of behavior and cognition in close interaction with other disciplines.

## Comparator, The

Jessica X. Brooks<sup>1</sup> and Kathleen E. Cullen<sup>1,2</sup>

<sup>1</sup>Department of Physiology, McGill University, Montreal, QC, Canada

<sup>2</sup>Biomedical Engineering, The Johns Hopkins University, Baltimore, Maryland, USA

### Definition

The theoretical concept of a “comparator” has been proposed in order to explain how the brain distinguishes sensory information that is expected based on our own voluntary behaviors versus that generated by events in the external world. Specifically, the comparator is thought to subtract the motor-based estimate of sensory inflow from actual sensory signal to suppress the representation of expected stimuli. This self-monitoring mechanism ensures accurate motor control and stable perception.

### Overview

It is important to correctly detect our own actions in order to effectively interact with and build an accurate representation of our environment. However, our sensory systems are activated by both external events (sensory exafference) and our own actions (sensory reafference). The prevailing view is that the brain largely achieves control of posture and accurate perceptual representation of the environment during voluntary actions by suppressing self-generated sensory stimulation. Notably, the reafference principle proposed by von Holst and Mittelstaedt (1950; see also the reafference principle section in this publication) posited that the motor command signal splits into two processing streams: one projecting directly to the effector (motoneuron generating the action) and the second to a comparator, which then subtracts the motor-related signal from the sensory input (see Fig. 1a). This second motor-related signal is termed an efference copy (or alternatively corollary discharge) signal (for reviews see Sommer

and Wurtz 2008; Cullen 2011). Effectively, by sending a copy of the motor command to sensory areas, the comparator computes the difference between the sensory input and motor-based efference copy signal. This difference represents the component of the sensory input that was not generated by the voluntary action. In this way the brain is able to distinguish sensory information due to external factors (exafference) from sensory information arising from our actions (reafference).

### Comparator Examples

Over the past many decades, models of comparators have refined the reafference principle to more fully explain sensory processing. At the behavioral level, studies investigating the perception of self-generated versus externally applied tactile stimulation have provided insight into why one cannot tickle one’s self (Blakemore et al. 1998). Further combined behavioral and imaging experiments suggested that the cerebellum is involved in predicting the specific sensory consequences of movements and that this signal is compared to the incoming tactile information to cancel the sensory response to self-generated stimulation.

Another important example of a comparator-based model of the reafference principle comes from neurophysiological studies of the cerebellum-like structures of the electrosensory systems of mormyrid and gymnotid fish and the Elasmobranchii (reviewed in Bell et al. 2008). Notably, the afferents in these electrosensory systems are strongly driven by both exafferent and reafferent changes in electric field strength. In contrast, central neurons (i.e., the Purkinje-like principal cells of the mormyrid and gymnotid fish electrosensory lateral line (ELL) lobe and dorsal octavolateral nucleus (DON) neurons of the Elasmobranchii) are insensitive to reafferent changes in electric field strength produced by (i) electric organ discharge in mormyrid fish, (ii) tail bending in gymnotid fish, and (iii) ventilation in Elasmobranchii. Over the last decade, a series of elegant studies

**Comparator, The, Fig. 1** Comparator models. **(a)** Simplified scheme of the reafference principle of von Holst and Mittelstaedt. The motor command is sent to the effector muscle, and in turn sensory activation, resulting from the activation of sensory receptors by an effector, is returned. This reafference is then compared to an efference copy of the original motor command. Here, reafference is arbitrarily marked “+,” and the efference copy is marked “−.” When the reafference and efference copy signals are of equal magnitude, they cancel, and no sensory information is transmitted to the next levels of processing. By contrast, a difference between the reafference and the

efference copy indicates an externally generated event (i.e., exafference) that is considered behaviorally relevant and thus is processed further. **(b)** Comparator-based model to explain the mechanisms underlying vestibular reafference suppression. In this model, the brain generates an expectation of sensory feedback based on an efference copy of the motor command to move the head and compares this expectation to the actual sensory feedback; if these two signals match, an inhibitory signal is sent to vestibular-only (VO) neurons in the vestibular nuclei and to the rostral fastigial nucleus of the cerebellum to cancel the incoming reafferent vestibular signals

in mormyrid fish have provided considerable insight into the mechanism underlying the suppression of reafferent electrosensory information. Specifically, individual ELL neurons integrate incoming electrosensory information with actively generated (i.e., predictive) proprioceptive cues and corollary discharge signals. When electrosensory information is temporally paired with these predictive inputs, this induces synaptic

changes such that over time the neurons stop responding to the paired electrosensory information. When the electrosensory information is removed, this results in the production of a negative image of the response to the electrosensory stimulus when it had been presented before the synaptic changes had occurred. In this way, the predictable electrosensory stimuli are filtered out thus enhancing unexpected sensory stimuli.

Neurophysiological studies of the vestibular system have further provided evidence for comparator-based mechanism underlying the suppression of self-generated vestibular stimulation in rodents and monkeys. Specifically, a comparator-based mechanism was found in which the vestibular system selectively encodes unexpected versus expected self-motion even when they occur simultaneously (Brooks and Cullen 2014). Notably, vestibulospinal pathways selectively respond to unexpected self-motion, thereby ensuring adjustments to postural tone in response to any head movements that the brain does not expect during voluntary movements such as locomotion. This selectivity is vital, for recovering from tripping over an obstacle while walking or running, which requires a robust postural response. In addition, the vestibular thalamocortical pathway also preferentially encodes unexpected motion, to ensure perceptual stability during active versus externally generated motion (reviewed in Cullen *in press*). Recent experiments suggest that the brain contains an internal forward model that expressly represents the relationship between voluntary action (efference copy) and the sensory consequences (Brooks et al. 2015) consistent with previously proposed theoretical models (e.g., Wolpert and Miall 1996, Fig. 1b). In such models, the comparator explicitly determines the difference between the brain's prediction of the sensory consequences of the action and the actual sensory inflow. This difference is known as the sensory prediction error. In contrast, in the original comparator-based model of von Holst and Mittelstaedt (1950), an efference copy of the motor command is used to directly suppress the sensory consequences of voluntary motor actions.

Finally, comparator models have also been used to explain the origin of our sense of agency (reviewed in Haggard 2017). Our sense of agency is defined as the subjective awareness of initiating, executing, and controlling our own volitional actions in the world. If a sensory event is the result of our own action (and if the brain's internal predictive model is correct), the actual sensory feedback will exactly match the forward model's prediction, and the result of the comparison is zero. However, if a sensory event is not due to

our action, there will be a non-zero prediction error indicating that we are not the causal agent of this event. Thus it has been proposed that the sense of agency is caused by the lack of any prediction error, implying absence of any signal at the output of the neural comparator for a specific act. In fact both humans and monkeys have demonstrated that they are able to distinguish self-generated from externally generated cursor movements on a screen, demonstrating a sense of agency that relies on perceptual (visual) cues (Couchman 2015) suggesting that a comparator-like mechanism may be contributing to their sense of agency.

## Compass Orientation

Dmitry Kishkinev  
Bangor University, Bangor, Gwynedd, UK

Compass orientation, in zoology, is the ability of animals to choose and maintain a particular direction using natural cues. Compass orientation

should be contrasted with *navigation*. The latter is a behavior of higher complexity when an animal first needs to detect its own position relative to a destination and then chooses a goal-ward (compass orientation) direction using any available directional references. Thus, compass orientation alone is not enough for goal-finding (*navigation*) in unfamiliar territories where a “map sense” is required to compare the animal’s current position to its destination. *Alignment* is similar in definition to compass orientation but is differentiated by the ability of an animal to maintain a specific angle of its body axis relative to a directional cue and not necessarily during the animal’s movement (e.g., alignment of a resting animal parallel to the Earth’s magnetic field). Compass orientation is usually studied in the context of animal migration but the ability to find directions is useful for any kind of animal movements, over short or long-distances, in migrating and sedentary animals.

Compass orientation deploys *compass mechanisms* that are cognitive and behavioral processes used by animals to choose and maintain directions. For instance, animals can use the apparent position of the Sun or sun-related cues (a sun compass), the stars (a star compass), the directional parameters of the Earth’s magnetic field (a magnetic compass), landmarks, and other directional cues for compass orientation.

The *sun compass* uses apparent position of the Sun as a directional reference (Schmidt-Koenig et al. 1991 for review). To keep a constant compass direction, the animal has to correct an initially chosen direction relative to the Sun’s position, while taking local daytime into account. Several studies suggested that birds (e.g., homing pigeons, *Columba livia* forma *domestica*) first have to learn how the Sun’s position is changing during the daytime and associate particular positions with local daytime hours. Once learnt, the sun compass can be used throughout the bird’s lifetime. Key evidence for the use of an internal clock with sun compass orientation includes time-shift experiments where pigeons with artificially manipulated internal biological time make directional mistakes during homing flights in sunny weather approximately corresponding to the degree of induced time-shift (15° for every 1 h shift). Additionally, there is experimental

evidence that birds can derive the Sun's position when the Sun cannot be directly seen (e.g., a partly cloudy sky and/or at sunrise/sunset) using sun position related light polarization patterns (Muheim et al. 2006).

The *star compass* is the ability to use stars for compass orientation and has been demonstrated in a range of animals (e.g., birds, fish, and insects). Most of these studies suggest that the star compass is a time-independent compass relying on visual recognition of particular stars (e.g., the North Star in the Northern Hemisphere) and/or their combinations. Stephen Emlen's studies in the 1960s and 1970s (e.g., Emlen 1967a, b) suggested that the star compass is not innate but rather requires learning. In his experiments, juvenile indigo buntings (*Passerina cyanea*, a North American nocturnal songbird migrant) were exposed to various artificial starry skies in a planetarium before the first autumn migration, and the bird's star orientation was tested in round arenas during the following autumn migration. Hand-reared experimental birds before their first autumn migration observed a starry sky at the night-time in a planetarium and learnt to recognize a particular star at (or near) the center of a starry sky's rotation, no matter whether it corresponded to the situation in the wild (i.e. whether it was the North Star or another star) or was unnatural stars and constellations. These birds used the learnt center of rotation as a directional reference in experiments during their first autumn migration. Time-shift manipulations do not appear to affect the star compass in birds species tested so far (e.g., Pakhomov et al. 2017). Therefore, the star compass is considered a time-independent compass.

The *magnetic compass* uses the direction of Earth's magnetic field as a directional cue and has been demonstrated in a wide range of animal species (Wiltschko and Wiltschko 1995; Kishkinev and Chernetsov 2015 for reviews). Some studies have argued that the magnetic compass is innate and does not require learning whereas others have suggested that the learning process is required to calibrate (i.e., compare) directions derived from the Earth's magnetic field against direction derived from astronomical cues (stars and the Sun). The magnetic compass can be either

polar or magnetic inclination based. The former can distinguish a direction toward the magnetic North Pole from that toward the magnetic South Pole, whereas the latter can only distinguish a direction toward a magnetic pole from a direction toward the magnetic equator. In most parts of the Northern Hemisphere, a poleward direction is approximately toward the geographic North and an equatorward direction is approximately toward the geographic South whereas in the Southern Hemisphere the poleward and equatorward directions are reversed. Most of avian studies have suggested that birds possess an inclination compass whereas mammals seem to have a polar one.

The sun and star compasses are thought to be vision based, however the sensory substrate of the magnetic compass is not fully understood. One line of research hypothesizes that the avian magnetic compass, so far the most studied one among the animals, is perceived visually, and cryptochromes (CRY) – a family of light-sensitive proteins found in avian retinal photoreceptors – are assumed to play a crucial role in the use of the magnetic compass. The Radical Pair Hypothesis (RPH) states that a CRY molecule gets excited through light absorption and an electron transfer reaction occurs inside the molecule forming a radical pair (RP) in which a CRY molecule and its partner have an unpaired electron each. The quantum properties of this RP and its dependent cascade of chemical reactions in the photoreceptor are both affected by the direction of the ambient magnetic field. If a photoreceptor were imagined as a "pixel" composing part of the visually perceived world, then this pixel's brightness would be dependent on the direction of ambient magnetic field line relative to the photoreceptor cell's orientation. Such signal modulation may ultimately enable birds to literally "see" the Earth's magnetic field, perhaps as visual patterns superimposed on the normal visual field. Proposed in the early 2000s, the RPH was initially hard to conceive. However, there is a growing body of experimental, though so far indirect, evidence supporting the RPH. One line of evidence comes from studies reporting that the avian magnetic compass is light-dependent because birds' ability to use magnetic compass

depends on a wavelength of the light to which a captive bird performing magnetic orientation is exposed. Caged birds appear to be unable to magnetically orient under red light but do it under the light of longer wavelengths (e.g., green and blue). The RPH explains this effect by energy transfer of photons: red light photons with relatively low energy cannot bring CRY molecules into a (magnetosensitive) excited state whereas photons of higher energies (e.g., green or blue) can. The second line of evidence comes from a bird brain study which suggests that lesions of Cluster N, a part of the avian forebrain active in dim light conditions, in European robins (*Erithacus rubecula*) leads to inability to use the magnetic compass. At the same time, Cluster N lesioned European robins were able to use the sun or star compasses and did not show any obvious vision deficiencies (Zapka et al. 2009). This suggests that the avian visual system is somehow involved in magnetic orientation. The third line of evidence for the RPH comes from the studies reporting a disturbing effect of broadband electromagnetic (EM) noise (0–10 MHz) in magnetic orientation of captive songbirds. Surprisingly, even EM noise of very low amplitudes can disturb captive birds' magnetic compass orientation in round arenas (a standard method to record orientation of migrating birds). Such an effect would be hard to explain if a magnetoreceptor were based, as alternatively assumed, on magnetized particles because such weak EM noise would have very little, if at all, effect on them. The RPH explains this EM disturbance as a resonance effect on unpaired electrons caused by the EM field, which theoretically can occur even at low amplitudes. One should mention that the RPH still lacks direct experimental evidence for the existence of CRY-based magnetoreceptors. Further, some predictions of the RPH have become recently criticized by a few biophysical modelling studies failing to explain the disturbing effect of extremely low-amplitude EM fields on the magnetic compass (Kavokin 2017).

The alternative hypothesis explaining the magnetic sense (whether it is directional sense or only the sense of magnetic field's strength) suggests the existence of magnetoreceptive cells based on

magnetized particles assumingly associated with the trigeminal nerves (the fifth pair of cranial nerves in vertebrates). Effects of brief, strong magnetic pulse on birds' orientation have been repeatedly reported since the 1990s, and they could be indirect evidence for this hypothesis. Such magnetic pulse treatments may affect (e.g., remagnetize) magnetic particles, if such existed in the bird's body. Indeed, changes in birds' orientation after magnetic pulsing have been documented, both in captive and freely migrating birds, though the mechanism of it remains unknown. Overall, one should mention that no magnetoreceptive cells have been demonstrated in the animals so far with certainty despite a few (not independently confirmed) reports in the last 20 years. Therefore, it appears to be premature to conclude how the animal magnetic compass sense exactly works.

Besides the aforementioned and most studied compass cues, there are data suggesting that animals can use the Moon, sounds, landmarks, and odour plumes (or gradient of various chemicals) for choosing and maintaining directions. Most of the animals can use a set of compasses together comprising a *compass system*. Often, multiple directional cues providing conflicting results are available to the animal at the same time. Therefore, different animals use different rules of compass hierarchy and compass calibration, i.e., how directional information is transferred from one directional cue to others. A few recent studies have suggested that in migratory songbird species a hierarchy between astronomical (the sun and stars) and magnetic compasses can greatly vary between species (Chernetsov 2017 for review).

## Definition

A test method for determining individual dominance ranks and the linearity (i.e., transitivity) of dominance hierarchies – especially of laboratory mice (also known as the tube-test). It was first designed by Lindzey et al. (1961) to determine differences in dominance abilities between mice of different inbred strains. The task allows for clear scores of dominance: “win,” “loss,” or “tie,” which are otherwise difficult to quantify by home-cage observations (Benton et al. 1980; Brain 1980, 1981). Some groups have expanded “win/loss/tie” outcomes, by recording the subtle behaviors mice show while interacting in the tube, including stillness, push-initiation, push-back, resistance, and retreat (Zhou et al. 2017).

## Method

To perform the task, mice are simultaneously placed on opposite ends of a long narrow tube to assess which mice consistently retreat in a face-to-face conflict. The tube is too narrow for the mice to pass by one another or turn around, thus at least one of them must retreat and exit the tube. The first mouse to retreat is given a score of “loss” and the partner subsequently is scored with a “win.” If both mice simultaneously retreat, they are given the score of “tie” – the occurrence of a tie is rare. Partners are usually tested consecutively for several trials (at least four), alternating the side of the tube. The mouse that consistently “wins” is considered dominant, and the mouse that consistently “loses” is considered subordinate – for the respective pair.

The CE task is typically administered using a round-robin tournament for mice housed together to determine the rank order of the group (Benton

et al. 1980). The tournaments can be divided into pair-tests and trials. Each pair-test consists of four consecutive trials between a pair of cage-mates, and members of the pair cannot be tested in an immediately consecutive pair-test. For instance, the first pair-test may include mouse A and B, and the second pair-test may include mouse C and D, but the second pair-test cannot include mouse A or B. Once all possible pairs are tested on a single-day, the tournament is complete. Consecutive tournaments are then administered across consecutive test days to determine whether the recorded rankings are stable (Wang et al. 2014).

## Task Validity

The task has been validated by determining whether rankings measured in the CE task converge with rankings measured in home-cage behavior, urine marking assay, food competition, and courtship vocalization (Greenberg et al. 2014; Howerton et al. 2008; Wang et al. 2011, 2014), although not all measures of dominance necessarily converge (Benton et al. 1980).

Further validation of the task is critically lacking. First, it is unclear whether the task is more likely to accurately measure stable ranks than unstable ranks. Since its inception, researchers often only consider stable dominance ranks in the CE test as true reflections of their dominance rank in the home-cage. This is problematic because mice are known to have unstable dominance ranks (Uhrich 1937), especially in despotic hierarchies, which are composed of a stable alpha and subordinates with unclear or unstable rankings. This methodological bias toward stable ranks is usually justified through reasoning that the measures must be reliable. However, it is possible to detect instability in a reliable manner if enough trials are given (albeit this has its own caveats; see second point). Reflecting this bias, mice with unstable ranks in the CE task have been systematically excluded from some studies measuring the relationship between dominance and brain function (e.g., Wang et al. 2011).

Second, the practice of consecutive testing may result in trained “dominants” and “subordinates” (Bernstein 1981; Wilson 1968). Social learning – or, training – is fundamental to the existence of dominance; however, learning in the CE task may be unique to the task itself and not representative of learned dominance in the home-cage (Miczek and Barry 1975). However, because the experience of dominance in one domain (e.g., home-cage) is not independent of that measured in other domains (e.g., CE task), programmatic experiments delineating this relationship remain to be performed. The evidence suggests, however, that this task is a measure of a novel dominance relationship. Specifically, mice need consecutive days of testing to gain enough experience with the test to reflect their dominance hierarchies as after a certain number of trials the probability of trained “dominants” and “subordinates” has been shown to increase (Varholick et al. 2018).

Third, it is likely that this task is largely affected by experimenter handling. For each trial the experimenter must simultaneously transfer mice to opposite ends of a tube, and then transfer the mice to a holding chamber before starting the next trial. If mice are not extensively familiarized to the handling procedure or are averse to their handler, their behavior in the tube might be more related to their response to the handler, rather than their response to the partner mouse. For instance, mice that are averse to their handler and subordinate may not readily retreat in the tube when “pushed” by the dominant partner. They could recognize the tube as a shelter, where the handler cannot handle them. Thus, individual mice may behave differently in the test depending on the handler. Again, this could be programmatically investigated but might be impossible to fully eliminate or control. Additionally, because this task requires an experimenter who observes the outcome of each trial, it is impossible to discount experimenter bias effects in the collection of data from each trial. These include subtle differences in the way the experimenter may handle, place, or otherwise conduct a trial having observed the outcome of the previous trial(s).

Fourth, it is worthwhile to consider whether the task appropriately acknowledges the biology

of the mouse. Specifically, mice have some ability to recognize familiar and unfamiliar individuals through odors and major urinary proteins (MUPs) (Hurst et al. 2001). Whether the mice can effectively perceive this odor, or any other odor for individual identification, before responding appropriately within the task – by retreating or pushing – remains unstudied.

Although the highlighted issues may perturb some investigators from using the task, the task can be useful for some experiments. If a research question is limited to stable dominance ranks, then it is likely that the stable ranks measured in the CE task are representative of the true dominance rank – provided the trials are not leading to trained “dominants” and “subordinates.” Also, the task may be useful for determining mice ranked alpha, because they are more likely to remain stable. In sum, one must weigh the costs and benefits of administering the task for their particular research question.

## Use Beyond Laboratory Mice

The task has also been used for other species beyond the common laboratory mouse. Several groups have used a similar test in rats (Carlini et al. 1974; Hsiao and Schreiber 1968; Miczek and Grossman 1972; Spigel et al. 1972; Wilson 1968), prairie voles (Anacker et al. 2014), and piglets (Székely et al. 1983). Some groups have also utilized the test to provide a measure of aggressivity for individuals in a controlled situation (Klomberg et al. 2002) – albeit the test was initially devised to study dominance, which is a representation of a relationship, not a trait of an individual.

## Synonyms

Complementation; Genetic Inheritance; Intergenic Complementation; Intragenic Complementation; Multiple Gene Inheritance

## Definition

Genes may produce different phenotypic effects when they are present together in an organism than either of the genes would have produced if they were present separately in an organism.

Complementary genes combine to produce unique phenotypic effects that would not be expressed if either of the genes were isolated in a separate organism. Complementary genes often exist at distinct genetic loci, either on different genes or on different sites within the same gene.

Simple examples of the effects of complementary genes include innocuous phenotypic effects such as the purple grain coloration in wheat observed by Dobrovolskaya et al. (2006). Additionally, White et al. (1996) showed the complementary effects of genes for eye color in *Drosophila melanogaster*. Further, Cornel et al. (1997) observed that the gene for red eye pigmentation in *Drosophila melanogaster* has a complementary effect in white eye strains of *Aedes aegypti*, resulting in red eye pigmentation. In this sense, complementary genes may only appear to be a chance occurrence, resulting when an offspring happens to inherit a particular combination of genes from each of its parents, and which usually generates no significant fitness benefits. However, some research has focused on fitness benefits that may be a result of complementary genes and the ways in which individuals of some species might select mates based on their potentially complementary genes.

## Mate Selection

Research has focused on the potential for complementary genes to result in offspring who bear an immune resistance to a unique array of pathogens from either of that offspring's parents. In a meta-analysis observing the effects of constrained mate choice in several species (e.g., cockroaches, fruit flies, mallards), Gowaty et al. (2007) found that offspring viability was higher when parents were allowed to mate with their preferred partners than when mate choice was experimentally

constrained. The researchers explained that, in addition to selecting mates based on physical indicators of good genes, individuals may also select mates based on the possible complementary gene effects of immune resistance, thus resulting in offspring that are less likely to die of infection.

### Complementary Genes and Mate Selection in Humans

Roberts and Little (2008) reviewed studies that investigated the ways in which humans select mating partners, and specifically, aspects of human mate selection that may have evolved as a way of selecting immune resistant partners. In particular, Thornhill et al. (2003) observed that men preferred the scent of women who had dissimilar (relative to similar) major histocompatibility complexes. Although the researchers did not observe a similar preference for women, they did observe a preference for the scent of men with high facial symmetry in ovulating women. The results suggest the possibility that men may use olfactory cues to select as mating partners women with a distinct immune resistance from themselves. Selecting mates with a dissimilar major histocompatibility complex may increase the likelihood of producing offspring with an increased resistance to infectious diseases.

At a glance, complementary genes might simply refer to the resulting phenotypic expression produced by two or more genes that, separately, would produce different phenotypes than when they occur in the same body. However, research investigating the selection of mating partners that is potentially based on complementary genes suggests greater complexity. Namely, individuals of some species may use cues to complementary genes in potential mates to produce offspring with an advantage in the form of increased pathogen resistance.

## Computerized Testing Paradigm in Primates

Melany Love<sup>2</sup> and David A. Washburn<sup>1,2</sup>

<sup>1</sup>Covenant College, Lookout Mountain, GA, USA

<sup>2</sup>Georgia State University, Atlanta, GA, USA

### Synonyms

[Language Research Center Computerized Test System \(LRC-CTS\)](#); [Psychomotor Test System \(PTS\)](#); [Rumbaughx](#); [Video-task paradigm](#)

The computerized testing paradigm is a general methodology for comparative research and environmental enrichment. Computer-graphic stimuli are presented to the test subjects, and responses are made using a touchscreen, joystick, or other manipulandum in accordance with the rules of game-like tasks. The paradigm has become one of the most popular methods for conducting psychological tests with humans and many species of non-human primates, as well as various other animals.

### Personal Computers for Nonhuman Animals

The computerized testing paradigm emerged as a result of three parallel and interconnected developments in the last quarter of the twentieth century. The first and perhaps most obvious catalyst was the introduction of commercially available personal computers (PCs). These early home computers provided opportunities for word processing, calculating, record keeping, and game-playing from the desktop. The 1970s and early 1980s saw tremendous growth in the video-game industry, led by arcade-based games but with a rapidly rising sector of dedicated game systems (e.g., Atari) and PC-game software (Wolf 2008). Psychological scientists quickly recognized the potential of this technology, using computers both to control traditional research apparatus and also directly *as* research apparatus, by

programming simple tests for cognitive and learning studies for adults and children. Shortly thereafter, the technology was also applied to understand the nature and limits of animal learning. Stimulated in part by the observation that chimpanzees seemed to enjoy playing joystick-based commercial games (Savage-Rumbaugh 1986), game-like variations on common test procedures such as matching-to-sample and two-choice discrimination learning were programmed in increasingly sophisticated tests of chimpanzee cognition.

### Psychological Well-Being

In addition to these technological innovations, a legal development also catalyzed the growth of the computerized testing paradigm with non-human primates. For researchers working in the United States with these animals, 1985 witnessed an important amendment to the Animal Welfare Act: The Improved Standards of Laboratory Animals Act mandated that research facilities uphold new standards for the psychological well-being, as well as the physical welfare, of their subjects. Primate researchers everywhere scrambled to understand how to provide “an adequate physical environment to promote the psychological well-being of nonhuman primates” (Public Law 99-198, Food Security Act of 1985, Subtitle F – Animal Welfare). In effort to comply with this amended law, researchers at the National Aeronautics and Space Administration (NASA), which had long employed rhesus monkeys (*Macaca mulatta*) as an animal model of the physiological effects of space travel, contacted Professor Duane Rumbaugh of Georgia State University’s Language Research Center (LRC) for consultation. Rumbaugh described his use of the computerized testing paradigm with joystick-using chimpanzees. There were empirically sound reasons from research with the Wisconsin General Test Apparatus to doubt that macaques could learn the remote cause-effect relations required to respond to stimuli on a computer display by manipulating

a spatially discontinuous joystick (see review by Rumbaugh et al. 1989); however, Rumbaugh reasoned that the benefits would be great if he and his colleagues could succeed in training monkeys on the computerized testing paradigm. In 1986, Rumbaugh’s team of investigators developed a configuration of apparatus and a suite of training software to teach rhesus monkeys to use the computerized testing paradigm. Whereas chimpanzees could learn by observation alone to control a computer-graphic cursor by manipulating a joystick, macaques required a carefully designed, systematic training curriculum to learn – but they *could* learn, and quickly demonstrated skillful performance on the paradigm. In this way, Rumbaugh and collaborators developed a test system that would “contribute to better treatment – as well as better understanding – of several subject populations” (Richardson et al. 1990, p. 130). The resulting apparatus, henceforth referred to as the Rumbaughx (pronounced “rum-box,” to parallel the naming convention of other influential apparatus innovations in comparative psychology, such as the Thorndike problem box or the Skinner box), provided environmental enrichment that allowed for flexible, affordable testing under conditions that promoted the psychological well-being of those animals (Washburn 2015).

The original design criteria for the Rumbaughx (see Table 1 of Richardson et al. 1990), including that the apparatus be user-friendly, customizable, and easily integrated with new and existing technologies, remain today and are largely responsible for the continued utility of the testing paradigm. For hardware, the Rumbaughx test station featured equipment that was (and still is) accessible for most researchers. A computer equipped with a color monitor and speakers was housed in a secondary enclosure so that only the handle of a joystick was accessible from an animal’s home cage. Working computers that are several years old (e.g., refurbished systems or those that might otherwise be surplussed) are typically more than adequate as computerized test systems. Commercially available pellet or juice dispensers are used to reward the animals automatically. The

curriculum of training software rewards the animals initially for any joystick movements, and subsequently for increasingly precise manipulations to bring the computer-graphic cursor into contact with a target stimulus on the screen. Task difficulty is automatically titrated on the basis of performance, such that the task gets harder when an animal is doing well, and gets easier if the animal begins to struggle. Across training steps, the monkey transitions from lever-pressing with the joystick, to directing the cursor into contact with stationary targets, to using the cursor to catch moving targets, to learning to discriminate the “correct” (rewarded) target from among several on screen, and so forth, building a repertoire of task-related skills that the animal can switch between flexibly and appropriately. (Animals trained with a touchscreen rather than a joystick progress through similar stages, but with more of a key-peck than a bar-press as the initial step.) Experimenter-specified parameters and menu options allow the tasks to be tailored further to the needs of a specific animal or a particular study. Stimuli include simple shapes and characters, computer-generated patterns, clip-art images, photographs, sounds, or any other computer-compatible media that are formatted properly (Richardson et al. 1990). The software records all accuracy, latency, and topography data for subsequent analysis. Whereas these might seem like standard features to today’s researchers, they were nothing short of revolutionary for research with nonhuman primates 30 years ago.

The advantages of the Rumbaughx included that the monkeys learned and performed the tasks with little human interaction and no deprivation from food or fluids (e.g., Rumbaugh et al. 1989; Washburn et al. 1989). Monkeys did not have to be reduced in body weight for purposes of testing, but rather could have the computerized testing system available continuously, working or resting whenever they wanted. Transfer of joystick-manipulation skills to novel tasks proved to be relatively straightforward, even in instances when the manipulation of the joystick yielded different outcomes, as in the LASER task, in

which joystick movement resulted in the aiming and shooting of a beam at the target (Washburn et al. 1989). Tasks such as these are much easier to implement with computers than with manual apparatus, and it seems likely animals show competencies with computer-task testing that would not be demonstrated with manual apparatus. It seems unlikely, for example, that chimpanzees could have revealed the same impressive memory for numeral sequences without the computer-task paradigm (e.g., Inoue and Matsuzawa 2009). It seems possible, but remains to demonstrate empirically, whether new competencies may be observed with the Rumbaughx because of factors like the large number of computerized stimuli, the consistency of computer-based presentations, the speed of responding on the computer, or even changes in the cognitive competencies of animals that have been trained to master the remote stimulus-response relations required for computer-based testing.

The computerized testing paradigm also delivered on its original promise to promote the psychological well-being of its test animals (see Washburn 2015, for a more comprehensive discussion). The monkeys willingly engaged the game-like tasks and, unlike the pattern that is seen with many manipulanda or puzzles used as environmental enrichment (e.g., Bennett et al. 2016), continued to show interest in the computer tasks across months and even years. They engage in computer-task activity even when there are other favorite toys or activities available; more important, task-directed activity replaced relatively maladaptive behaviors in the animals’ repertoires. That is, access to the Rumbaughx resulted in fewer stereotypies, bouts of overgrooming or self-injurious behavior, aggression, distress vocalizations, and related signs of compromised psychological well-being (Washburn 2015). Given the opportunity, the animals direct attention to the tasks for many hours each day, leaving fewer hours for behaviors indicative of boredom or distress. Although the food rewards provided by the computerized testing paradigm clearly contribute to this sustained

interest – from one perspective, the joystick paradigm is a repeating problem box or foraging manipulandum that automatically replenishes itself – monkeys have been shown to work even when the food pellets were made freely available, and to prefer working for the food than receiving the food freely (Washburn and Rumbaugh 1992b). These game-like tasks provide individually calibrated levels of challenge and stimulation to the test animals. Given the option, the monkeys will elect to perform a variety of different tasks, and not only the easiest and most rewarding options (Washburn and Rumbaugh 1992b). The system also affords unprecedented options for the animals to control when and on what they work. Perdue and collaborators (2014) reported that the monkeys “choose to choose”; that is, they prefer to have such choices. These factors, combined with the compatibility of the system with primates’ health and social needs, make it an enrichment device that taps all four components of primate psychological well-being (comfort, companionship, challenge, and control; see Washburn 2015).

## The Rise of Comparative Cognition

Given its usefulness for enrichment and the rich corpus of data that it produces, the computerized testing paradigm quickly attracted the interest of researchers at other laboratories, and these scholars were freely provided copies of the training software and instructions for assembling the Rumbaughx. The apparatus has since been successfully implemented with many species, including lemurs, squirrel monkeys, capuchin monkeys, baboons, orangutans, bonobos, dogs, bears, elephants, pigs, rats, and many other species (e.g., Andrews 1993; Croney 1999, as cited in Marino and Colvin 2015; Hyatt 1998, 2013; Merritt et al. 2007; Vonk et al. 2012; Washburn et al. 2004), and for the purposes of studying such diverse topics as visual illusions, perception and action, attention skills, concept formation, episodic memory, mental rotation, learning, numerical

cognition, metacognition, self-regulation, symbol learning, prospective memory, social cognition, brain-behavior relations, and many other constructs (for a review, see Beran et al. 2016; see also Beran et al. 1998; Evans and Beran 2012; Leighty and Frigaszy 2003; Parr and de Waal 1999; Parr et al. 1998; Templer and Hampton 2013; Smith et al. 2012; Vauclair et al. 1993; Washburn 1993).

This breadth of topics studied with the Rumbaughx highlights the third catalyst to the development and popularity of the computerized testing paradigm: the rise of comparative cognition. A shift in theoretical focus was already underway in the 1980s when the new technology was applied to the study of animal behavior. The so-called cognitive revolution within experimental psychology was increasingly evident in comparative psychology (e.g., Wasserman 1993), and the field was ready for a general and flexible testing paradigm that could be used to explore a range of cognitive topics with a range of animals. The operant chamber or Skinner box has served the field with distinction, allowing researchers to strip away variables that complicate our understanding of learning and to focus on the stimulus, response, and reinforcement contingencies themselves; however, comparative cognition recognizes the need to embrace these complexities in order to understand the processes that may mediate and moderate the stimulus-response associations. With the computerized testing paradigm, virtually every test procedure from cognitive psychology, developmental psychology, comparative psychology, and clinical neuropsychology could be translated into game-like tasks for use with primates and other animals.

As scientists worldwide began to examine animal behavior through use of the computerized testing paradigm, innovative refinements to the apparatus and procedures were introduced. Rumbaugh and his colleagues had initially hedged their bet by training two rhesus monkeys on a joystick-based system, and a third monkey with a touchscreen-response system. The monkeys’ impressive performance with the joystick

paradigm led the research team to abandon the prohibitively expensive touchscreen technology (Washburn et al. 2017). As touchscreens have become more affordable in recent years, an increasing number of researchers have adopted touchscreen paradigms derivative of the Rumbaughx for use with nonhuman populations, including monkeys, pigeons, and rats (e.g., Drayton and Santos 2014; Fagot and Bonté 2010; Hampton and Hampstead 2006; Kangas and Bergman 2017; Mandell and Sackett 2008; Markham et al. 1996; Spetch et al. 1992). Innovations that permit computer-based testing on socially housed nonhuman primates (e.g., Fagot and Paleressompoulle 2009; Gazes et al. 2013) represent another critical methodological advance in the way that cognition is studied comparatively.

## Summary

Washburn et al. (1994) reported that for many years, comparative psychology trailed far behind other sciences in terms of its use of computer technology: In the 1970s, over 80% of the apparatus used in popular comparative journals of the time were variants of operant and maze devices, and of the small percentage that reported computer use, most was limited to the storage and maintenance of data. By 1989, the Rumbaughx was installed in dozens of facilities and in use with hundreds of nonhuman primates (Washburn and Rumbaugh 1992a). Today, computer technology has so saturated the comparative research environment in the USA and abroad that it is difficult to calculate how many facilities use variations on the computerized testing paradigm – and where indeed to draw the line between the traditional Skinner box and the Rumbaughx-like variation in which rats touch or pigeons peck computer-graphic stimuli on a touchscreen (e.g., Bussey et al. 2008; Cook et al. 2004; Sawa et al. 2005; Wasserman et al. 1995; Wolf et al. 2014). Further advancements in comparative psychology are undoubtedly pending as even newer technologies

surface (e.g., Dolins et al. 2017). With each opportunity, there must also be discussion of how each apparatus or paradigm might slant results or produce artifactual findings. That is, each new way to ask research questions also provides new constraints on the kinds of answers are obtained. The operant chamber, for instance, revolutionized the study of learning by simplifying the stimulus-response contingencies; however, the simplification that made the apparatus ideal for identifying the effects of reinforcement on behavior also limited the kind of learning that could be studied to relatively simple stimulus-response types. Related consideration of species differences in the suitability of an apparatus for different species is also important: Whereas the joystick paradigm has been used with species other than nonhuman primates, many of the nonprimate species (or even some species across the primate order) have disadvantages with respect to perceptual, motor, or other factors. For example, although rats were able to learn basic joystick-control skills (Washburn et al. 2004), the time this required combined with the animals' relatively short lifespans severely limited the range of cognitive tasks that could be introduced after this training. Discussion of these concerns, coupled with a healthy reluctance to rely too heavily on a particular method or apparatus, will promote development of a comprehensive catalog of tools that researchers can use to characterize animal behavior – a catalog in which the Rumbaughx, and the computerized testing paradigm more broadly, enjoys a position of prominence.

## Concordance

Surajit Bhattacharjee and Avik Sarkar  
Department of Molecular Biology and  
Bioinformatics, Tripura University,  
Suryamaninagar, Tripura, India

### Synonyms

Compliance; Congruence

### Definition

The term concordance defines as a manifestation of the same characteristic in both members of a twin pair (Smith 1972; Lewontin 1982). When the both the members of the twins have or lack a same trait then they are concordant. Identical twins are the ideal example of concordance.

**Concordance rate** is a measurement using statistical index that analyzes the relative effect of nature (which signifies the traits which are being inherited) and nurture (signifying the qualities and traits which are acquired in a lifetime) assessed altogether. Concordance rate is a

statistical index employed by the geneticists to describe the probability rate that two individual with shared genes will develop the same organic disease.

Alternatively, Hrubec proposed that the extent to which the twins tend to be concordant, that is, the extent to which the disease tends to occur in both members of twin pairs, is generally measured by concordance rates (Hrubec 1973).

### Essentiality of Concordance Study

Geneticist compares the concordance rate of identical twins to that of fraternal twins in order to decipher whether a disease or a certain trait has a genetic cause or not (Smith 1972). In identical twins analysis, the genetic makeup carried by one would very likely also be carried by the other which makes them genetically virtually identical. There is a high probability that a particular trait caused by a certain gene identified in one twin may also be present in the other twin (Smith 1972).

The twin method study is often not given the privileges or significant attentions as they deserve. Very little documentation is available since its applicability in twin study. This is partly because of the variety of statistical methods used for concordance analysis and the different genetic interpretations made on this basis in many cases erupts out as ambiguous. The probable reason for this ambiguity generally lies on the lack of expertise in statistical analysis by the users (Smith 1974).

Many of the clinical geneticists have reported about the particular characteristics of the twin concordance (Allen et al. 1967; Bulmer 1970 and Smith 1972). For example, Irving I. Gottesman and James Shields, psychiatric geneticists, conducted the behavioral genetic study among the twins to depict the concordant rate in schizophrenia, which they have published in 1972 (Gottesman and Shields 1972, 1976).

### Models for Studying Concordance

Several authors have manifested many of the suitable statistical analysis for determining

concordance. Zdenek Hrubec (1973) uses different analytical methods of concordant for assessing the involvement of genetic factors in disease etiology with the perspective of diagnosis of twins. He also describes the concordance of disease probability between the twins to identify the extent of the disease occurrence in both members of the twin pairs based on random and conditional ascertainment model. Very similarly, C. Smith has documented the use of pro-band concordance rate analysis to depict the frequency of liability between the twins (Smith 1974).

Diagnosis of twins is generally assumed to be done independently among the members who have visited the clinics. The disease diagnosis process in a twin pair may be evolved in two different ways, either (i) when the patients directly report for presence of a particular disease to a clinician or (ii) a disease symptom may accidentally come into clinician’s notice during thorough clinical investigations.

On this perspective two different models have been proposed to observe the disease alternatives (Hrubec 1973). Henceforth, the evaluation of incomplete diagnostic strategy is being determined on two basic models like:

- **Random Ascertainment Model**
- **Conditional Ascertainment Model**

A Simple Example of Concordance Study

The concordance rates can be calculated and used for data analysis as follows:

Fifty pairs of similar twins and 50 pairs of fraternal twins are chosen for concordance analysis. The collection of the twins will be in such a way that one twin in each pair will exhibit the disease morbidity. Now, for instance, if only one twin in a pair shows morbidity then the twins will be designated as **discordant** for morbidity. On the other hand, **concordant** for morbidity is said to exist when both of the twins in a pair exhibit the disease.

Next, two concordance rates can be calculated: one for identical twins and the other for fraternal twins (Table 1). The pairwise concordance rate analysis can be applied for this study.

**Concordance, Table 1** shows the number of concordant and discordant pairs assumed among the selected identical and fraternal twins

|                 | Number of concordant pairs | Number of discordant pairs | Total number of pairs |
|-----------------|----------------------------|----------------------------|-----------------------|
| Identical twins | 20                         | 30                         | 50                    |
| Fraternal twins | 12                         | 38                         | 50                    |

C<sub>I</sub> = The rate for identical twins

$$C = \frac{\text{Number of concordant Pair}}{\text{Number of concordant Pairs} + \text{Number of Discordant Pairs}}$$

First the pairwise concordance rate for identical twins has been calculated where the number of concordant identical twin pairs is 50 and the number of discordant identical twin pairs is 50.

$$C_I = \frac{20}{20 + 30} \times 100$$

$$C_I = \frac{20}{50} \times 100 = 40\%$$

Very similarly, calculate the pairwise concordance rate for fraternal twins.

The number of concordant fraternal twin pairs = 17

The number of discordant fraternal twin pairs = 83

C<sub>F</sub> = Rate for fraternal twins

$$C_F = \frac{12}{12 + 38} \times 100$$

$$C_F = \frac{12}{50} \times 100 = 24\%$$

Analysis of the Calculation

Thus, from this analysis it is found that concordant rate between the identical twin is 40% whereas the rate between the fraternal twins is

24%. These values justify the rate of pairwise similarity index for sharing a particular disease taken for consideration.

## Applications

- The concordance analysis generally confines on the pattern of heritability of a particular disease trait to offspring and to how far extent that genetic disease is being expressed between the twins.
- The study helps us to determine the linkage analyses for both MZ and DZ twin pairs taken for concordant evaluation.
- Quantitative genetic analyses and heritability assessment, encompassing correlations among concordance, can be used to investigate the relative importance of genetic and environmental influences on a particular trait (Lichtenstein et al. 2002).
- Analysis/comparison of concordance through quantitative genetic method can be applied to elucidate the importance of genetic and environmental impacts on physical traits.
- The concordance study is used to investigate the correlative index of different diseases from cardiovascular to any kind of neurological or behavioral disease among the twins.

## Drawbacks

- The genetic interpretation of many of the different measures of concordance is difficult and their value is questionable in many respects (Smith 1972).
- In a given genetic pattern there may be different phenotypic consequences in genetically identical individuals since it is not possible to have 100% penetrance.
- Developmental and environmental factors may not be identical for genetically alike individuals. If these factors contribute to the development of disease or other characteristic, there may be a chance for the evolution of distinct and nonsimilar traits; hence applicability of concordance will not be possible in this regard.

## Concluding Remarks

Concordance rate analysis in twin study estimates the correlation among twins in order to characterize the relation between a trait and the genetic factor. The correlation is genetically interpreted following the elimination of nongenetic ancestral effects on twins and calculation of the coefficient of genetic determination for the trait.

Mario A. Laborda<sup>2</sup> and Francisca Díaz<sup>1</sup>

<sup>1</sup>Universidad de Chile, Santiago, Chile

<sup>2</sup>Departamento de Psicología, Facultad de Ciencias Sociales, Universidad de Chile, Santiago, Chile

## Synonyms

Conditioned inhibitor; Pavlovian inhibition

## Definition

Conditioned inhibition (CI) refers to a phenomenon of associative learning in which a stimulus (a conditioned inhibitor) signals the absence of an unconditioned stimulus (US). More technically, a conditioned inhibitor is defined as a stimulus that passes both a summation and a retardation of acquisition test (see below).

## Introduction

Animals are constantly learning where to get food, safety, and comfort, through Pavlovian associations. They spend energy moving toward cues that signal appetitive outcomes and moving away from situations that predict danger. Interestingly,

as useful as it is to learn to look for food and to escape, it is to learn where and when not to, allowing the animal to save energy and effort. Environment cues can give us this type of information by signaling that an outcome will not occur right now. CI is the mechanism by which we can learn not to respond to those situations.

Within the frame of associative learning, CI has at least two meanings, it can refer to an experimental procedure that results in a conditioned inhibitor, and it can refer to the reduced responding associated with the presence of a conditioned inhibitor. Responses are usually elicited in the presence of a conditioned or unconditioned stimulus, but if a conditioned inhibitor is present, responses are reduced or might not even happen at all (i.e., they are inhibited by the conditioned inhibitor).

## Pavlov's Procedure for CI

Ivan P. Pavlov (1927) first proposed that a reduction of conditioned responding could occur in two ways: responding could be reduced by the presence of a novel stimulus (a phenomenon he denominated *external inhibition*), and it can be reduced by a previously trained stimulus, a phenomenon he called *internal inhibition*. The latter with time was renamed as *conditioned inhibition*.

In Pavlov's CI, trials of excitatory conditioning (in which a stimulus is followed by an unconditioned stimulus (US)) are interspersed with a second type of trial (inhibitory trials), in which the first stimulus is now presented in compound with a different stimulus, a second cue, in the absence of the US. Through this procedure Pavlov noted that the second stimulus became a conditioned inhibitor and that it could reduce responding to the first stimulus trained and also to another excitatory conditioned stimulus (CS), different from the one used to train the conditioned inhibitor (i.e., a transfer excitor).

As research on conditioned inhibition progressed, different experimental procedures for CI training were developed. For example, different to Pavlov's procedure, the to-be conditioned inhibitor can be presented alone during the

inhibitory trials (Lyons 1969) and the US and the conditioned inhibitor can be just present interspersed but never together (i.e., negative contingency; Rescorla 1969). These procedures may appear quite different, but they have in common that the conditioned inhibitor is always presented in the absence of the US. Thus, any stimulus signaling the absence of US may become a conditioned inhibitor, and the presence in training of a punctate excitatory CS might be irrelevant.

### Necessary Conditions for CI

At least two critical conditions must be met for CI learning to happen. The first one is that there must be an expectation of the US. A conditioned inhibitor cannot signal the absence of the US if the US is not expected by the animal in the first place. An excitatory CS typically establishes this expectancy of the US. In Pavlov's inhibition procedure, an excitatory CS creates the expectancy during the inhibitory trials, but the US is absent. This is a significant event for the animal, and the stimuli signaling it become important to learn about. In procedures where there is no excitatory CS, it is harder to identify the source of the expectancy of the US, but it is usually assumed that in those cases, the context or other non-discrete stimuli generate this expectancy.

The second condition is that the conditioned inhibitor must have a higher chance of happening without the US than with it. Outside the laboratory, CS rarely signals an event with perfect accuracy. This means that the conditioned inhibitor may occur in the presence of the US once in a while, but only if the chances of that are lower than the chances of the US occurring by itself. Both conditions are met by all the procedures previously described.

### Effects in Behavior of a Conditioned Inhibitor

The inhibitory status of a conditioned inhibitor is not always readily apparent. In some occasions, the strength of a conditioned inhibitor can be

measured directly by observing whether it reduces conditioned or unconditioned responses or not. This works well for responses that are bidirectional in nature. A response is bidirectional if it can increase or decrease from its baseline. For example, a well-documented bidirectional behavior is that of approach and withdrawal from CSs. Just like with food itself, an animal may approach a food-signaling CS. The elicited behavior in this case is appetitive. Notably, a conditioned inhibitor for food may become aversive because it is associated with the absence of food, eliciting withdrawal behavior. Measuring CI in these cases is straightforward, but not every behavior is bidirectional. For example, freezing is a common result of fear conditioning, and fear to a CS is indirectly measured by how much it reduces another behavior from baseline. As in this case, a conditioned inhibitor will not elicit behavior above baseline levels; different strategies have to be adopted to measure inhibition.

Pavlov demonstrated that two CS can summate their response levels if presented together. Similarly, a conditioned inhibitor can be tested in compound with another excitatory CS, a procedure denominated *summation test* (aka compound stimulus test or associative summation test). If the conditioned inhibitor is indeed inhibitory, responses to the compound would be lower than responses to the excitatory (transfer) CS alone. However, this test alone is not enough to be certain a stimulus is a conditioned inhibitor. A summation test can also be passed by a stimulus that commands higher attention than the excitatory CS. So, a summation test can be passed by a stimulus that is a conditioned inhibitor or another type of stimulus that somehow hoards attention from the animal. Because of this, a second test is usually used in conjunction with the summation test, a *retarded acquisition test* (aka retardation test). In this test, a supposed conditioned inhibitor is paired with the US, just like in Pavlovian excitatory conditioning. The inhibitory properties of the conditioned inhibitor are assumed to retard the rate of Pavlovian conditioning acquisition (or expression). Thus, if the conditioned inhibitor acquires excitatory strength slower than a neutral stimulus, then it passes the

test. A retarded acquisition test can also be passed by a stimulus that catches little attention. For example, a stimulus presented by itself before Pavlovian acquisition (i.e., before being paired with a US) also provokes slower acquisition of excitatory strength. This is called, somewhat confusingly, latent inhibition (Míguez et al. 2015; Reiss and Wagner 1972). This is different from conditioned inhibition in that a preexposed cue does not predict the absence of a US or any relevant consequence. It regards little attention, passing a retardation test. This circles back to the summation test, as a low attention stimulus would fail it. Both tests are used under the assumption that a stimulus cannot have high and low attention at the same time. This allows us to conclude that a stimulus is inhibitory, discarding alternative explanations for the effect of a conditioned inhibitor on behavior (Cole et al. 1997; Polack et al. 2012).

## Theories of Conditioned Inhibition

There are mainly three ways to understand how CI works (Savastano et al. 1999). The first one assumes that conditioned inhibition and excitation are opposite poles of a continuum. The second one proposes that inhibition is a separate and parallel process to excitation. The third one assumes that inhibition is a result of behavior, that is, it occurs at the level of performance instead of the associative level.

The continuum theories come from total-error-correction theories of Pavlovian conditioning such as the Rescorla-Wagner model (Rescorla and Wagner 1972), in which stimuli have a predictive value to a US, and animals learn by the correction of this value during conditioning trials. A stimulus paired with a US gains positive associative value toward it, whereas a stimulus paired with the absence of a US gains negative associative value and becomes a conditioned inhibitor. This kind of theory readily explains both summation and retardation tests. When paired with a US, a conditioned inhibitor needs to correct its negative value to neutral and then to positive values, and so it acquires positive associative value

slower than a neutral stimulus, which moves directly from a neutral to a positive value. Also, when presented with an excitatory CS, the negative value of the conditioned inhibitor counteracts the positive value of the excitatory CS, provoking less responding than to the excitatory CS alone. If the stimulus is not a conditioned inhibitor, it would have neutral or positive value, so the net sum would be equal or higher than the excitatory CS alone.

A second family of models accounts for CI in a different way. In this family, CI is a parallel process relative to conditioned excitation; although the predictive learning rules between them are similar, it assumes an inhibitory association, separate from the excitatory one, as result of that process. For example, Konorski (1967) posed that behavior is influenced by both positive associations between the CS and the US representations and positive associations between the CS and no-US representation. In the retarded acquisition test, a conditioned inhibitor must acquire a stronger US association than its no-US association, showing a weaker CR acquisition. In the summation test, both US and no-US associations compete simultaneously, resulting in low CR.

The third family accounts for behavior indicative of CI without assuming the existence of inhibitory associations. An example of them is the comparator hypothesis (Miller and Matzel 1988). For this model, conditioned responding is the result of a process involving a comparison made in the moment of performance. There are no inhibitory processes, and the strength of stimulus associations is always positive. The associative strength of a stimulus is compared to that of a comparator stimulus. In Pavlov's inhibition procedure, the comparator is the excitatory CS. When a conditioned inhibitor is presented, it is compared to its comparator stimulus, and because the strength of this comparator stimulus is much higher than that of the conditioned inhibitor, it produces little conditioned response. In other types of CI procedures where there is only a US present, the background cues (i.e., context) become the comparator. This can explain the retardation test, because the conditioned inhibitor must overcome the associative strength of its

comparator before it can produce a robust conditioned response. The summation test is also explained if it is assumed that two comparisons can summate the response potential that they each produce.

## Summary

In short, a conditioned inhibitor signals the absence of a US. This can be accomplished by pairing a stimulus with the absence of a US through different procedures, and it can be assessed with summation and retarded acquisition tests. Regarding the theoretical explanation for conditioned inhibition, it can be viewed as another pole of an excitation continuum or as the result of a different process.

## Conditioned Place Preference

Chana K. Akins<sup>1</sup>, Shannon E. Eaton<sup>2</sup> and B. Levi Bolin<sup>2</sup>

<sup>1</sup>Department of Psychology, University of Kentucky, Lexington, KY, USA

<sup>2</sup>University of Kentucky, Lexington, KY, USA

## General Introduction

The conditioned place preference (CPP) procedure has been widely used in pharmacology, learning, and behavioral neuroscience. Its most common, but not exclusive, application has been in studying the rewarding and/or aversive properties of drugs and as a screening tool for drug abuse potential (e.g., Bardo and Bevins 2000; Tzschentke 1998). Although there are many

methodological differences, the general CPP procedure consists of presenting a rewarding or aversive stimulus in the presence of one distinct chamber on one day and a neutral stimulus (e.g., vehicle) in another distinct chamber on alternating days. After several conditioning days, subjects receive a choice test that involves access to the entire apparatus without the presence of the stimuli. A CPP is established if subjects spend significantly more time in the compartment paired with the rewarding or aversive stimulus. If subjects spend less time in a compartment paired with a stimulus, they may be eliciting a conditioned place aversion (CPA). Whether or not a place preference or aversion occurs and to what degree depends upon numerous features of a CPP study including the apparatus used, the design of the study, and the methods. The current entry will briefly survey methodological considerations, applications of CPP for natural rewards and drug studies, and the brain mechanisms involved in CPP.

## Apparatus, Design, and Methodological Considerations

### Apparatus

**Two- Versus Three-Compartment Chambers** An important consideration of the choice of apparatus used in CPP studies is the number of compartments (Bardo and Bevins 2000; Tzschentke 1998). In a typical three-compartment CPP study, the outermost two compartments consist of distinct contextual features (e.g., grid versus cross-grid flooring), and a middle compartment has no special features. A rewarding stimulus is presented in one of the outermost compartments and a neutral stimulus in the other outermost compartment. The middle compartment is therefore not paired with either a rewarding or neutral stimulus. However, in a two-compartment CPP box, a subject has to choose between a compartment associated with a rewarding stimulus and one associated with a neutral stimulus, thereby requiring a “forced choice.” A forced procedure has the potential to bias a

subject toward or away from the compartment they were placed in during the test session.

One important difference between the two- and three-compartment procedures is that the middle compartment of the three-compartment apparatus is relatively novel on the test day, whereas neither compartment of the two-compartment apparatus is novel on the test day. Therefore, the novel compartment might appear to enhance CPP showing a reduction of time spent in the neutral compartment relative to the reward-paired compartment. This may result in a false positive since it assumes that the preference for novelty would reduce the time spent in the compartment paired with a neutral stimulus more so than time spent in the compartment paired with a rewarding stimulus.

### Design

**Biased Versus Unbiased Designs** Another important consideration in CPP studies is whether the design is a biased or an unbiased one (see Prus et al. 2009 for review). In a biased design, the initial preference of a subject for a particular compartment is assessed by measuring the amount of time spent in each compartment. The least-preferred compartment is then assigned to be paired with a rewarding stimulus. In an unbiased design, the assignment of a particular compartment for pairing with a rewarding stimulus is determined by the researcher regardless of the initial preference of each subject for either compartment.

**Pre-existing Preferences** Concerns about CPP procedures often involve the potential for pre-existing preferences for one environment over another that may alter conditioning processes (Bardo and Bevins 2000). An environmental context may be preferred before conditioning, and this may or may not alter the acquisition of a CPP. Many studies utilize a biased procedure in which the non-preferred compartment is used as the conditioning compartment to avoid misinterpretation of an initially non-preferred context. For example, a non-preferred context, prior to conditioning, could be interpreted as neutral compared to the preferred context or aversive. If the context is aversive, an increase in preference for

that context could be interpreted as less of an aversion rather than an increase in reward-related value of the compartment.

### Other Methodological Considerations

**Sensory Modalities** Sensory modalities are also an important issue in establishing a CPP because they take into account species-specific sensory capabilities. For example, in CPP studies with birds, visual stimuli such as colored walls of the chamber have been used (Levens and Akins 2001). This contrasts with the multimodal contextual cues (visual, tactile, olfactory) typically used with rats, a species that has a relatively poor visual capacity. Visually-based CPP in an avian species may offer some unique advantage in modeling conditioned drug effects that occur in the real world. For example, proximal or distal environmental cues associated with drug taking may attract abstinent drug users and cause them to seek out the drug and ultimately relapse. These environmental cues may be visual in nature.

**Drug Studies** There are additional methodological considerations of CPP that are specific to drug studies. One major consideration is in the identification and interpretation of what is learned in the CPP procedure. A common interpretation of an established CPP is that of Pavlovian conditioning, such that a distinct environment (conditioned stimulus or CS+) is paired with a rewarding or aversive stimulus (e.g., drug; unconditioned stimulus or US), resulting in increased time spent in that environment (conditioned response). Another distinct environment (CS–) is presented in the absence of the US. Bardo and Bevins (2000) describe processes other than reward or associative learning that might account for a place preference such as novelty/familiarity of contexts, state dependence, and anxiety. For example, an animal may receive equal exposure to both distinct contexts such that environmental familiarity appears to be equated in CPP experiments. However, if the drug of interest interferes with familiarization, then place preferences may reflect the tendency of rats to spend more time in a novel environment rather than a conditioned association

between the context and the rewarding effect of the drug.

Another consideration in drug CPP studies may be the number of conditioning trials. Depending on how potent the rewarding properties are of a reward-related stimulus, fewer and more conditioning trials may be needed to develop a CPP. For example, drugs that have potent rewarding properties such as amphetamine and cocaine may require fewer conditioning trials than drugs that have weaker rewarding properties, such as nicotine and ethanol (Tzschentke 1998).

### Application of CPP to Study Natural Rewards

The CPP procedure has been used to test the rewarding properties of a wide array of stimuli including food, wheel running, social interaction, and copulation. What follows is a brief overview of the application of CPP for each of these natural rewards.

**Food** Although food has been commonly used as an appetitive stimulus (one that is sought out) in behavioral studies, relatively few studies have specifically assessed the rewarding properties of food using CPP. Mace et al. (1997) tested Japanese quail chicks with a distinctly colored chamber paired with normal food and a different distinctly colored chamber paired with food tainted with methyl anthranilate (bird aversion chemical). When tested in the absence of both foods, quail chicks spent more time in the distinctly colored chamber that had previously been paired with normal food over the chamber previously paired with tainted food. In addition, the place preference for normal food over tainted food developed in as few as 2 days of conditioning. Similar findings have been reported in studies with rodents (e.g., Spyraiki et al. 1982) but without the colored walls.

An important consideration in studies examining food-induced CPP is the palatability of the food. Although the consumption of highly palatable foods such as a sucrose solution typically induces a CPP, more recent research has directly

compared food-induced CPP for highly palatable food versus standard laboratory diet. Using an unbiased CPP procedure in monkeys, Duarte and colleagues (2015) repeatedly paired one of two distinct contexts with chocolate chips (i.e., a high palatability food) and the other with standard diet (i.e., a food with comparatively less palatability) on alternating days. Compared to the preconditioning baseline, monkeys spent significantly more time in the context that was paired with the highly palatable food (i.e., chocolate chips) than in the context paired with a less palatable food (i.e., standard diet) during the test trial.

Although the majority of research on CPP has been conducted in nonhuman animal subjects, technological advances have created new opportunities for research on CPP in humans. In a recent study (Astur et al. 2014), participants were given chocolate candy (i.e., M&Ms) while they explored a distinct computerized virtual environment. On alternating sessions, another distinct virtual environment was presented in the absence of candy. The next day, participants completed a test session during which they had free access to both virtual environments through a neutral hallway. During the test session, participants spent significantly more time in the virtual environment that was paired with chocolate candy compared to the virtual environment that was not paired with candy.

**Physical Activity** Several studies have examined physical activity as a reward using CPP procedures. Lett and colleagues (2000) placed adult male rats that had been food restricted to 80% of their free-feeding body weight into enclosed running wheels for 2 hr. In a backward conditioning procedure (US before CS), rats were then removed from the running wheel (the US) and immediately placed into the appropriate conditioning chamber for 30 min (CS). On alternate sessions, rats were confined to a small chamber for 2 hr and then placed into the opposite conditioning chamber. Results showed that rats spent more time in the chamber that was paired with the residual effects of wheel running compared to the context that was not paired with the effects wheel

running. In contrast to these findings, a study using forward conditioning showed that rats developed a conditioned place aversion (CPA) to wheel running if they were placed into the conditioning chamber (CS) prior to a 60-min period of wheel running (US; Masaki and Nakajima 2008). These findings suggest that the rewarding properties of wheel running may differ depending on whether forward or backward conditioning procedures are used.

**Social Interaction** The CPP procedure has also been used to evaluate the rewarding properties of social interaction. In one of the earliest studies, Calcagnetti and Schechter (1992) employed a biased CPP procedure and showed that a play-induced CPP developed in socially dominant, individually housed (i.e., socially deprived) juvenile rats. Importantly, this CPP was induced following repeated pairings of the initially non-preferred context with a submissive, socially active conspecific that engaged in play behavior compared to the initially preferred context that was paired with a socially inactive partner that did not engage in play behavior because of treatment with scopolamine. More recent research on social interaction has focused on determining the effect of housing on CPP. In general, animals that are socially housed show a place preference for a chamber that contains other socially housed conspecifics.

**Sexual Behavior** Various aspects of copulation have been examined using CPP. In these studies, copulation with a conspecific is paired with a distinct chamber or given in the home cage just prior to exposure to a chamber. On alternating days, animals are taken directly from the home cage and are placed in the opposite chamber with no copulation. Both sexually naïve and sexually experienced male rats develop a CPP for a chamber where they have ejaculated with a female rat, but only sexually naïve males show a CPP for a chamber associated with intromissions (Tenk et al. 2009). These findings suggest that there may be hierarchy of rewarding components of sexual behavior with ejaculation being the most rewarding component.

Studies that have attempted to establish sex-induced CPP in female rats are more limited and have been less successful. Paced-mating behavior appears to be particularly important for the induction of CPP in female rats. For example, female rats that were permitted to pace the rate of a copulatory opportunity by a male rat showed a shift in preference toward a sex-associated context, but those that were not permitted to pace did not (Paredes 2009).

## Application of CPP to Study Drug Effects

CPP has been adopted to test the rewarding effect of a wide range of drugs, including legal, prescription, and illicit drugs in a wide range of species including humans, other mammals, amphibians, fish, birds, and invertebrates. Many drugs that consist of a rewarding component often have abuse potential. Therefore, it is important to identify drugs that have a rewarding component and to examine the magnitude of that reward. The current section will review CPP studies involving various drugs.

## Psychostimulants

**Cocaine** Cocaine is likely the most commonly studied drug in CPP studies. The rewarding properties of cocaine have been extensively examined (see Tzschentke 1998 for review). Early studies involved investigating parametric aspects of cocaine CPP and applying agonists/antagonists, while current studies are focused more on the cellular and neurobiological mechanisms such as with the role of various receptors and involvement of genes.

Females appear to be more sensitive to the rewarding effects of cocaine than males. Female rats develop a cocaine CPP at lower doses than males and in fewer sessions (Russo et al. 2003). This sensitivity to the rewarding effects of cocaine appears to be mediated by estradiol (E2) since cocaine CPP is attenuated in ovariectomized (OVX) females compared to gonadectomized males and females (Russo et al. 2003).

**Methamphetamine** Methamphetamine (METH) is a highly potent stimulant that produces prolonged euphoric effects. Based on this, one might assume that it has potent rewarding properties and that these would elicit a robust CPP. However, METH has been shown to induce both CPP and aversion, depending on the dose (Cunningham and Noble 1992). Also, the acquisition of METH CPP has been shown to require more pairings than needed for cocaine CPP (Zakharova et al. 2009).

While studies on sex differences and the rewarding effects of METH are sparse, reports have failed to find sex differences in METH CPP (e.g., Schindler et al. 2002). This is somewhat surprising given the differences between males and females in their response to cocaine.

**Amphetamine** Amphetamine (AMPH) is a strong stimulant that has been used medically for certain conditions; however, it does have some abuse potential. AMPH CPP has been demonstrated with both low and high doses and pretreatment with a dopamine antagonist blocked AMPH CPP (Spyraki et al. 1982). AMPH CPP has also been identified in humans. Childs and de Wit (2013) have shown that human participants rate AMPH-paired environments as more preferred and liked even if they rated it as the least preferred prior to AMPH administration (Childs and de Wit 2013). Therefore, AMPH CPP appears to be a fairly robust phenomenon.

## Opiates

The pain-relieving effects of morphine, a mu-opioid receptor agonist, are known to vary drastically between males and females. Both male and female rats develop a CPP to morphine (e.g., Karami and Zarrindast 2008). However, female rats develop a CPP with lower doses of morphine and have a more pronounced CPP at higher doses compared to males. Typically, as the dose of morphine is increased, males show reduced CPP but females continued to demonstrate morphine CPP at high doses. E2 appears to play a role in this increased sensitivity to the rewarding effects of

morphine since ovariectomizing female rats attenuates morphine CPP and E2 injections reverse this effect (Mirbaha et al. 2009).

Naloxone, a mu-opioid receptor inverse agonist, has become a primary treatment for individuals suffering from an opioid-induced overdose. In rodents, the effect naloxone has on morphine CPP is related to the time at which naloxone is administered. When naloxone is administered during conditioning, it blocks the acquisition of a CPP, whereas when it is administered on test day, it appears to enhance the expression of morphine CPP (Neisewander et al. 1990). Additionally, although naloxone pretreatment during conditioning attenuates the rewarding effect of morphine in both males and females, at a high dose males demonstrate an aversion (Karami and Zarrindast 2008).

## Ethanol

It is commonly accepted that the effects of ethanol are dose dependent with higher doses resulting in less inhibition and more sedative-like effects. With regard to CPP, low doses typically fail to demonstrate CPP, moderate doses elicit a CPP, and higher doses typically elicit an aversion (e.g., Torres et al. 2014). While ethanol-induced preferences and aversions have been well established in rats, results have been inconsistent due to strain differences and route of administration (see Fidler et al. 2004 for review).

In general, rodent studies suggest that females may experience greater rewarding effects of ethanol compared to males. Torres et al. (2014) found that an intermediate dose of ethanol induced a CPP in female rats but not in males or ovariectomized females, the latter suggesting the role of ovarian hormones. Additionally, a high dose of ethanol resulted in a CPA similarly in male and female rats (Torres et al. 2014).

## Nicotine

Nicotine (NIC) CPP studies in rodents have yielded mixed results. Some studies have found

dose-dependent CPP, while others have found no effect or CPA. It is evident that NIC CPP studies are readily influenced by methodology, strain, route of administration, and other issues (see Tzschentke 1998 for review). For example, several studies that have compared biased and unbiased CPP procedures have found that NIC has to be paired with the animal's initially non-preferred chamber to produce significant CPP (see Le Foll and Goldberg 2005 for review). In addition, NIC administration can produce either anxiolytic or anxiogenic effects that might alter the expression and/or interpretation of CPP.

NIC is one of the few drugs studied that may be more rewarding in males compared to females. Both age and sex appear to play an important role in the induction of NIC CPP, such that adolescents are more sensitive than adults to the rewarding effect of NIC and males are more sensitive to the rewarding effects than females (e.g., Vastola et al. 2002).

## Cannabinoids

**THC**  $\Delta$  (delta) 9-Tetrahydrocannabinol (THC) is the psychoactive ingredient in smoked cannabis. Research regarding the rewarding effects of THC in animals has yielded inconsistent results, with some research indicating no rewarding or aversive effects, some indicating a CPP, and some a CPA. While these discrepancies may be due to a number of factors including dose and timing of administration, another factor may have to do with the aversive qualities of THC. However, Hempel et al. (2016) have shown that reduction of residual aversive effects of THC does not mask or attenuate its rewarding effects. Therefore, it is possible that THC may have weak rewarding effects that do not support CPP.

## MDMA

3,4-Methylenedioxymethamphetamine (MDMA), also known as ecstasy, has recently been under investigation for use in the treatment of post-

traumatic stress disorder and other anxiety disorders. It is also commonly abused alone or in combination with other drugs in “rave” settings. It is therefore important to understand its reward value and abuse potential. Male mice and rats demonstrate a CPP for an MDMA-paired chamber (e.g., Daza-Losada et al. 2007), and it can be reversed by naloxone, rimonabant, and tropisetron (Braida et al. 2005).

### **Application of CPP as a Drug Screening Tool**

A relatively recent consideration for the use of CPP has been with regard to evaluating medications (Napier et al. 2013). Many FDA-approved pharmacotherapies for drug dependence tend to target direct effects of drugs of abuse rather than learned associations that cause craving and relapse. Because CPP involves the formation of learned associations between a drug and contextual cues, it may serve as a promising tool to identify treatments for drug addiction that reduce the expression of CPP (Napier et al. 2013).

### **Neurobiological Mechanisms of CPP**

Although a comprehensive discussion and review of research on the underlying neurobiological mechanisms of CPP is beyond the scope of this entry, the literature collectively suggests that they are complex and varied. This is further complicated by the fact that the specific neural and molecular substrates involved in CPP are likely to be specific for that particular stimulus. One of the few relatively unifying themes that emerges from the CPP literature is that central dopamine systems are thought to play a critical role in the development and expression of CPP, especially in the case of drug-induced CPPs (see Tzschentke 1998 and Prus et al. 2009 for reviews). In many cases, natural stimuli and drugs that stimulate dopamine activity (e.g., sex and cocaine) in the mesocorticolimbic pathway also induce CPP. The mesocorticolimbic pathway is widely accepted as critical for reward and reinforcement learning and

is composed of neural projections from the ventral tegmental area into the prefrontal cortex and limbic structures like the nucleus accumbens, hippocampus, and amygdala. In many, but not all cases, the development and/or expression of CPP may be blocked by the administration of compounds that antagonize dopamine receptors (e.g., haloperidol) or can be attenuated or abolished by lesions of these neural structures. However, the view that dopamine in the mesocorticolimbic pathway is primarily responsible for CPP is drastically oversimplified. Previous research has also implicated other neural structures (e.g., the hypothalamus, ventral pallidum, and pedunculopontine tegmental nucleus) and a wide range of neurotransmitters including serotonin, norepinephrine, acetylcholine, glutamate, GABA, orexin, ghrelin, leptin, oxytocin, and steroid hormones in CPP for drugs and natural rewards (e.g., Tzschentke 1998). Therefore, one of the major challenges for understanding the neurobiology of reward is that more comprehensive frameworks are needed that better organize and integrate our current understanding of the factors and processes that mediate reward processing.

### **Conclusions**

In conclusion, the CPP procedure is a fairly ubiquitous procedure mainly used to investigate rewarding and aversive properties of naturally rewarding stimuli and drugs. It is primarily used in rodent studies but has been modified to use in a variety of species ranging from flatworms to humans. The procedure has many advantages including allowing for testing both rewarding and aversive stimuli, testing the preference when the animal is in a drug-free state, and modeling some aspects of human drug use. Unfortunately, the procedure is hindered by methodological challenges and can result in inaccurate data due to habituation/novelty effects and/or anxiolytic effects of drugs. Furthermore, it is difficult to generate dose-effect information. In spite of these challenges, CPP studies continue to be on the rise and the applications for CPP are increasing.

## Confusion Effect

Carsten Schradin

Université de Strasbourg, CNRS, IPHC UMR 7178, Strasbourg, France  
School of Animal, Plant and Environmental Sciences, University of the Witwatersrand, Johannesburg, South Africa

## Definition

The reduced attack-to-kill ratio of a predator resulting from its inability to single out and catch an individual surrounded by other individuals. In other words, it is more difficult for predators to capture prey that is surrounded by other conspecifics than to capture an isolated individual.

## What Is the “Confusion” in the Confusion Effect?

The term “confusion effect” implies that the predator experiences difficulties in concentrating on one out of several moving individuals because the predator is confused by the movements of many similar-looking individuals. This implies cognitive problems to attend to multiple targets. Neural network models give support for the confusion effect (Krakauer 1995). In psychology it has long been known that humans have problems in concentrating on two tasks at once. Attention is thought to be a function with limited capacity. The more similar two tasks are, the more difficult it is to concentrate on them simultaneously. Several prey individuals moving around present multiple tasks that a predator could concentrate on and may thus overtax the predator’s ability to divide its attention. On the other hand, dealing with this task might be costly, as then less attention is available for other tasks. For example, hungry sticklebacks that preyed on daphnia swarms of high density detected a predator dangerous to themselves less often than sticklebacks preying upon a swarm of low density (Milinski 1984). This was interpreted as an inability of the nervous

system to give attention to several tasks at once (prey and own predator) and thus a cost of overcoming the confusion effect by paying less attention toward the potential presence of a predator. Neural network models demonstrated that the decrease in attack success by sticklebacks corresponded to an increase in spatial targeting error with larger group size, which depended mainly on the number of individuals in the group, not density (Ioannou et al. 2008).

### The Confusion Effect Contributes to “Safety in Numbers”

Safety in numbers refers to the benefit of being part of a group in the case of a predation event. The confusion effect represents one benefit of group living, reducing the chance of successful predation. The confusion effect contributes to “safety in numbers” together with increased vigilance (a group will discover a predator sooner than a single animal), the dilution effect (when a predator kills only one group member, the probability for a specific individual to be the victim is the smaller the larger the group is), the encounter effect (decreased probability of predator encounter per individual as detection of larger groups does not increase proportionally with group size), and the group defense (a group can defend itself better against a predator than a single individual). All individuals of the group benefit simultaneously from the confusion effect, with minimal costs. Thus, grouping due to the confusion effect can be considered as a form of mutualism, i.e., a form of non-altruistic cooperation.

### Examples of the Confusion Effect

Because the confusion effect is one out of several advantages leading to safety in numbers, it is difficult to be studied separately. Even though in both aquatic and terrestrial group-living species, the confusion effect has often been claimed to be one important benefit of group living, this has been hard to demonstrate, as confounding effects of vigilance, encounter effect, and group defense

were seldom controlled (Krause and Ruxton 2002). Nevertheless, several studies found support for the confusion effect. These studies demonstrated either that the predator’s success decreased with increasing group size or that predators preferably attacked small over large groups. Three-spined sticklebacks (*Gasterosteus aculeatus*) preferably attacked a tube containing only 2 daphnia (*Daphnia magna*) compared to a tube containing 40 daphnia (Milinski 1977). Largemouth bass (*Micropterus salmoides*) rapidly captured single silvery minnows (*Hybognathus nuchalis*), but their success decreased as the school size of minnows increased (Landeau and Terborgh 1986). Similarly, jacks (*Caranx ignobilis*) easily captured single Hawaiian anchovy (*Stolephorus purpureus*) but were less successful in capturing individuals in schools (Major 1978). And finally, the attack success per encounter with a prey (different species of fish) decreased for squids (*Loligo vulgaris*), cuttlefish (*Sepia officinalis*), pike (*Esox lucius*), and perch (*Perca fluviatilis*) as the prey’s school size increased (Neill and Cullen 1974).

One experimental study performed in captivity with a reptilian and a primate predator was able to control possible confounding variables, finding clear support for the confusion effect (Schradin 2000). The prey (mealworms and black beetles, *Tenebrio molitor*) was harmless and had no chance of predator avoidance. Thus, confounding effects of group defense and enhanced vigilance were controlled. Both leopard geckos (*Eublepharis macularius*) and common marmosets (*Callithrix jacchus*) took longer to catch one out of several prey compared to one single prey. Leopard geckos also showed more fixations (changing of head position) when confronted with 20 mealworms than when confronted with only 1 mealworm, showing indications of being “confused.” This was not the case in common marmosets, which probably moved their eyes instead of their head, which was not measured. In sum both leopard geckos and common marmosets took longer to capture one prey out of a group of harmless prey that could not avoid predation and thus could not benefit from increased vigilance or the encounter effect (Schradin 2000).

## Dazzle Camouflage Enhancing the Confusion Effect

Dazzle camouflage refers to a form of camouflage where dazzles do not conceal the individual but make it more difficult to estimate the individuals speed and heading. This is thought to be the case in many animals having stripes, such as striped mice (*Rhabdomys pumilio*), chipmunks (*Tamias* spp.), and zebras (*Equus* spp.). While this hypothesis remains largely untested in wild living mammals, computer games where humans had to track striped targets moving in groups showed that dazzle camouflage enhances the confusion effect: it was harder for humans to track striped than non-striped targets (Hogan et al. 2016). Whether high-contrast patterns may benefit animals in groups by enhancing the confusion effect remains to be tested.

## Dissimilarity Is Weakening the Confusion Effect

The confusion effect describes that it is more difficult for a predator to capture prey that is surrounded by other conspecifics than to capture an isolated individual, because it cannot focus on a single individual as it is confused by the many individuals moving around. Thus, the confusion effect is expected to be especially strong when all individuals look the same. In contrast, if one individual sticks out because it looks different, the predator might be able to focus at this single individual and thus overcome the confusion effect. This has been called the oddity effect. It has often been assumed that odd individuals, for example, white (albinos) or oddly moving (old or injured) individuals, are especially targeted by predators, maybe because focusing on them overcomes the confusion effect (Krause and Ruxton 2002). Experimental studies coloring prey, such as daphnia or fish, found empirical evidence that the confusion effect is weaker when individuals are visually distinguishable from others (Krause and Ruxton 2002). Importantly, even odd individuals benefit from grouping, as their risk to be predated is still lower than that of a single individual (Landeau and Terborgh 1986).

## Conclusion

The confusion effect is one benefit of group living with respect to predator avoidance: it is more difficult for predators to capture prey that is surrounded by other conspecifics than to capture an isolated individual. Predators of different taxa suffer from the confusion effect: cephalopod, fish, reptilian, and mammalian predators all suffer from the difficulty of capturing a single prey out of a group simply because it is surrounded by other moving conspecifics. As the confusion effect is an ultimate cause in the evolution of group living, advantages for prey not yet living in groups and disadvantages for predators not used to group-living prey must exist as soon as the prey starts grouping (Schradin 2000). The confusion effect can thus yield immediate advantages when solitary-living prey starts to form groups, thus confronting the predator with a new problem.

## Definition

Bacterial conjugation is the transfer of genetic information between bacterial cells by a bridge-like connection between two cells.

## Introduction

Conjugation is a process that promotes DNA transfer from a donor to a recipient cell mediated by physical contact (Cavalli et al. 1953; Hayes 1953). Bacterial conjugation is the mechanisms of horizontal gene transfer between two bacterial cells. Conjugation represents a key constituent in the spreading of antibiotic and virulence genes to human pathogenic bacteria.

Usually, genes encoding a factor for conjugation are present in an extrachromosomal replicon termed a self-transmissible or conjugative plasmid. The conjugation is a phenomenon of fundamental evolutionary and ecological consequence. T-DNA of Ti plasmid-mediated transfer from *Agrobacterium* species to plants appears to represent a novel form of bacterial conjugation (Lessl and Lanka 1994). DNA transfer is conciliated by membrane-associated macromolecular machinery called Type IV secretion system (T4SS). T4SSs are also involved in the transport of virulence factors by pathogenic bacteria.

The mechanism of conjugation can be divided into three functional components: the coupling protein, relaxosome, and a type IV protein secretion system. Bacterial conjugation is a course of sexual reproduction but not identical to sexual reproduction because it does not involve the fusing of gametes and the creation of a zygote. At the wide and narrow range, some of the plasmids could be transferred (R751 and F, respectively) from *Escherichia coli* to *Saccharomyces cerevisiae* (Heinemann 1991; Dürrenberger et al. 1991).

## Evidence of Bacterial Conjugation

The evidence of bacterial conjugation was performed by a well-designed experiment of Joshua Lederberg and Edward Tatum in 1946. They used two mixed auxotrophic bacterial strains and incubated the culture for several hours in the nutrient medium and then plated it on minimal medium. They used double and triple auxotrophs. One strain needed biotin (Bio-), phenylalanine (Phe-), and cysteine (Cys-) for growth,

and another required leucine (Leu-), threonine (Thr-), and thiamine (Thi-). After incubation, prototrophic colonies appeared on the minimal medium. As an outcome, the chromosomes of the two auxotrophs were able to join and go through recombination.

Lederberg and Tatum did not directly confirm that contact between the cells was necessary for gene transfer. The evidence of physical contact between cells was proved by Bernard Davis (1950). In their testing, they constructed a U-tube consisting of two pieces of curved glass tube fused at the base to form a U-shape with a fixed glass filter between the halves. The filter permitted the passage of only media but not bacteria. The U-tube was filled with nutrient medium and each side inoculated with a different *E. coli* auxotrophic strain. Through incubation, the medium was pumped back and forth through the filter to ensure medium exchange between the halves. After 4 h incubation, the bacteria were placed on minimal medium. Davis revealed that when the two auxotrophic strains were divided from each other by the fine filter, gene transfer could not take place. Therefore, Lederberg and Tatum had observed that direct contact was required for the recombination.

F- recipient cells is believed to be investigated by an interaction between the tip of an F pilus and the recipient cell surface (Novotny et al. 1968; Ou and Anderson 1972). There is evidence for the occurrence of DNA transfer between cells that were not in surface contact, but there is also both indirect and direct confirmation that conjugating cells are typically aggregated in close wall-wall association (Ou and Anderson 1972; Harrington and Rogerson 1990). After DNA transfer is finished, mating cells actively disaggregate (Achtman et al. 1978) to produce two cells that capable of donor activity (Fig. 1).

The first surface association of donors and recipients in aggregates is thought to reflect pilus retraction, mediated by depolymerization of the pilus subunit, into the donor and/or recipient cell envelope (Panicker and Minkley 1985). These donor and recipient contacts then become stabilized in a way to renders the aggregate more resistant to shear forces (Achtman et al. 1978). Recipient cells carrying mutations altering the structure of the lipopolysaccharide (Anthony et al. 1994) or the outer membrane protein OmpA (Skurray et al. 1974) also affect F- donor cell interactions, but it is unclear.

## F-Conjugation Process

The functioning of F factor mediated gene transfer was studied in liquid matings through the F- conjugation system. Contact between F<sup>+</sup> donor and

## Pull In and Push Out: Mechanisms of Horizontal Gene Transfer in Bacteria

In eukaryotes, transfer of genetic information from parent to their offspring via a core pathway

**Conjugation, Fig. 1** Showing the 5' nick is produced in plasmid DNA at oriT site which helps in transport from Donor cell F<sup>+</sup> to Recipient F<sup>-</sup> cell

of vertical gene transfer. In the case of bacteria and other prokaryotes, genetic information can also be transmitted between organisms via horizontal gene transfer and it is also known as lateral gene transfer (Keeling and Palmer 2008). Various genome-wide studies have shown that HGT occurs at a high frequency among prokaryotic species, mainly if they are closely related and present in the same environment or community (Beiko et al. 2005). HGT permits fast acquisition of a new function important for species adaptation and survival.

The advancement of the eukaryotic organism was marked by endosymbiotic events leading to permanent achievement of major cell organelles, e.g., mitochondria that originated from proteobacteria and plastids that originated from cyanobacteria, followed by organelle to nucleus gene transfer, generally referred to as endosymbiotic gene transfer (EGT) (Archibald 2015). Horizontal gene transfer (HGT) drives the transfer of antibiotic resistance genes (ARGs) serving an important role in the development of multidrug resistance (MDR) in bacteria (Forsberg et al. 2012). By means of HGT, the accumulation of genes involved in different resistance mechanisms from the exogenous DNA, bacteria are able to obtain MDR rapidly (Burton and Dubnau 2010; Syvanen 2012). For example, *Acinetobacter* and *Enterobacter* strains carrying the NDM-1 plasmid or *mcr-1* plasmid, which contain a group of resistance genes, can stand even last-resort antibiotics (Liu et al. 2016; Shen et al. 2016; Zheng et al. 2017).

There are three “traditional” methods of DNA transfer in natural history: bacterial conjugation, natural transformation, and transduction (von Wintersdorff et al. 2016).

### **Pull DNA in During Natural Transformation**

The first natural transformation was revealed in *Streptococcus pneumoniae* in 1928 (Griffith 1928). The DNA transfer during natural transformation is well conserved among Gram-positive bacteria, e.g., *Bacillus subtilis* and *S. pneumonia* (Berka et al. 2002) and Gram-negative bacteria

species (e.g., *Neisseria gonorrhoeae*, *Haemophilus influenzae*, and *Vibrio cholerae*), as well as archaea (Burton and Dubnau 2010; Johnston et al. 2014; Cabezón et al. 2015; Ilangovan et al. 2015, 2017; Veening and Blokesch 2017).

During natural transformation, Gram negative bacteria need to pull DNA across both the outer membrane (OM) and the inner membrane (IM), whereas Gram positive bacteria require overcoming the barrier of the peptidoglycan layer, which is much thicker and denser, and need to be weakened before translocation of DNA across the inner membrane (IM). In this process, dsDNA is pulled across the outer membrane (OM) in Gram negative bacteria and ssDNA is pulled across the IM in both Gram positive and Gram negative bacteria.

Exogenous DNA is pulled into the cytoplasm by the extension and pulling out of pseudopili, as a result of the assembly and disassembly of pseudopilin multimers (PilA). This is followed by the transfer of dsDNA transversely the OM protein PilQ/HofQ (for Gram negative bacteria only). The DNA receptor (ComEA) mediates the transfer of ssDNA across the inner membrane channel produced by ComEC with the help of the ATPase ComFA, accompanied by degradation of the other strand of DNA. The incoming ssDNA is protected by DprA which conveys it to RecA for homologous recombination in the cytoplasm (Fig. 2).

### **Push Out Mechanism for Transfer of DNA During Bacterial Conjugation**

During bacterial conjugation, DNA can be pushed out from one donor cell and transported into a recipient cell. A group of mobile genetic elements, known as integrative and conjugative elements (ICEs) or conjugative transposons (Franke and Clewell 1981), has been found in many bacterial genomes (Cury et al. 2017). The transfer of conjugative DNA across the membrane of the donor bacterium depends on a large membrane-associated protein complex that belongs to the type IV secretion system (T4SS) (Cabezón et al. 2015; Ilangovan et al. 2015).

Protein-coated conjugative ssDNA is transported across the IM, periplasm, and OM through

### Conjugation,

**Fig. 2** Showing the general mechanism underlying DNA transfer during natural transformation

a membrane channel formed by a group of proteins encoded by the conjugative DNA molecule (Ilangovan et al. 2015). Inside the channel, the conjugative pilus (formed by pilins) is responsible for pushing ssDNA out of the membrane. The process of DNA transfer through conjugation has been best exemplified by the Vir system. To export DNA out of the donor cell, a complicated membrane protein complex encoded by the conjugative plasmid. During conjugation, a plasmid or ICE encoded relaxase creates a nick in one strand of the conjugative DNA at the *oriT* site, followed by ssDNA translocation across the channel formed by components of the T4SS and replication of the remaining strand, either independently from or in concert with conjugation (Ilangovan et al. 2017). During translocation across cell membranes, three ATPases (VirD4, VirB4, and VirB11) provide the energy for DNA transport (Cabezón et al. 2015; Ilangovan et al. 2015).

Further, the transport of ssDNA, a group of membrane, and periplasmic proteins are assembled simultaneously to form a large complex, which can be subdivided into four different ways: (1) the pilus is formed by the assembly of pilins (VirB2) with adhesins (VirB5) at the distal end; (2) the OM component, which consists of VirB7, VirB9, and the C-terminus of VirB10; (3) the periplasmic component which consists of VirB8, VirB10, and VirB6; and (4) the IM component, formed of VirB3, VirB6, VirB8, and VirB10. Additionally,

three hexameric ATPases (VirB4, VirB11, and VirD4) are attached to the IM to provide energy during DNA transfer (Fig. 3).

### Potential Applications

The gene transfer from bacterium to eukaryote has a unique and highly significant application and potential in the evolution of modern eukaryotes, which divide mainly in two main areas: research and biotechnology (Lim et al. 2008; Lacroix and Citovsky 2016). Research applications principally aim at inventing new protein properties and cellular pathways by expressing specific genes of interest which delivering gene-targeting systems, such as CRISPR/Cas9 (Nekrasov et al. 2013) and insertional mutagenesis. Genomes of interest insertional mutagenesis, for example, generating T-DNA insertion mutant libraries of the model plant *Arabidopsis thaliana* (Alonso et al. 2003; Llosa and de la Cruz 2005; Sun 2018).

Several biotechnological applications of conjugation aim at expressing the specific genes/traits of interest, such as pathogen and abiotic stress resistance genes, antibiotic resistance gene, biofuels and pharmaceuticals production through genetically engineered pathways, or expression of desired phenotypes, e.g., color and fragrance of flowers and fruits in agriculture or restoration of normal cellular functions in gene therapy. To

**Conjugation,****Fig. 3** DNA transfer during bacterial conjugation using T4SS

achieve these wide-ranging goals to adapt and optimize diverse bacterial DNA transfer systems or even discover new species of bacteria that are capable of DNA transfer to eukaryotes or use as a vector for genetic transformation of specific eukaryotic cells or microorganisms, thus allowing development of highly efficient “customtailored” DNA transport tools for each specific application.

## Conclusion

Studies of gene transfer systems are significant for their latent ecological and evolutionary importance as well as for their process for the development of novel biological tools for fundamental and practical purposes. Hence, at the global level horizontal gene transfer may have been more important for the evolution of eukaryotes.

## Connectionist Network

### ► Neural Network

## Consciousness

Rocco J. Gennaro  
University of Southern Indiana, Evansville,  
IN, USA

This chapter will address the extent to which nonhuman animals are conscious. Most important perhaps is what criteria should be used in making such a determination. We have certainly come a long way from the Cartesian view that animals are mere “automata” and do not even have conscious experience. In addition to the obvious and significant behavioral similarities between humans and many animals, much more is known today about our neurophysiological and genetic similarities. Still, there are some grey areas and genuine difficulties in interpreting some experimental results pertaining to animal cognition and in analyzing the comparative neuroanatomy.

The more general “problem of other minds,” including the so-called argument by analogy, is introduced in the section “[Animals and the Problem of Other Minds](#)”. In the section “[Lloyd Morgan’s Canon and Parsimony](#),” “Morgan’s Canon” and the related principle of simplicity is addressed especially as they pertain to attributions of animal consciousness. The section “[More on Some Hard Cases and Brain Structure](#)” focuses on some of the

harder cases, such as fish and insects, where it is necessary to delve more deeply into some comparative neurophysiology. Finally, in the section “[Animal Consciousness and Higher-Order Thought Theory](#),” the charge that one prominent philosophical theory of consciousness (the higher-order thought theory) is inconsistent with animal consciousness is explored. Here the focus is on the possibility of self-awareness and meta-cognition in animals.

Philosophical and scientific work on animal minds and consciousness has surged in recent years with the publication of several major studies and reviews, such as Tye (2016), Andrews and Beck (2018), Allen-Hermanson (2018), as well as the recently launched on-line journal *Animal Sentience* (see, e.g., Harnad 2016, Klein and Barron 2016; see also Allen and Trestman 2016, Andrews 2016). Much of this work takes on the challenge of the most difficult borderline cases, such as reptiles, crabs, insects, and fish, as well as further examination of the evolution of consciousness.

Perhaps the most commonly used notion of “conscious” is captured by Thomas Nagel’s “what it is like” sense (Nagel 1974). When I am in a conscious mental state, there is “something it is like” for me to be in *that state* from the first-person point of view. When I smell a rose or have a conscious visual experience, there is something it “seems like” from my perspective. This is primarily the sense of “conscious state” that I use throughout this chapter. Ideally, we would like to know which, and to what extent, animals are capable of having conscious subjective experiences such as pains, perceptions, and emotions. As Nagel famously asked, “What is it like to be a bat?”

## Animals and the Problem of Other Minds

It is clear that we have come a long way from the Cartesian view that animals are mere “automata” and that animals do not even have conscious experience. Other major figures in the early modern period, such as Leibniz, also struggled with the question of animal (or “brute” or “beast”) consciousness (Gennaro 1999). There has indeed

been a long history of philosophical opinion and argument about animal consciousness (see, e.g., Allen and Trestman 2016; Allen-Hermanson 2018). In addition to some clear behavioral similarities between humans and many animals, much more is known today about other physiological similarities such as brain and DNA structures. To be sure, there are also important differences and some genuinely difficult grey areas where one might have legitimate doubts about a given animal and consciousness. Nonetheless, it seems fair to say that most philosophers today agree that a significant portion of the animal kingdom is capable of having conscious mental states. Of course, this is not to say that animals can have *all* of the same kinds of sophisticated conscious states enjoyed by human beings, such as reflecting on philosophical and mathematical problems, enjoying artworks, or thinking about the vast universe or the distant past. However, it still seems reasonable to believe that animals can have at least some conscious states ranging from rudimentary pains and emotions to various perceptual states (visual, olfactory, tactile, etc.) and episodic memory.

One traditional way to approach this topic is via the “problem of other minds,” that is, how we can know that others have conscious mental states especially given the more indirect access we have to them as compared to our own minds. Although there is no generally accepted solution to this problem, most people in practice simply take it for granted that other *human beings* have mental states similar to theirs. However, knowledge of animal minds does present some particular difficulties. Nonhuman animals cannot describe their mental states using language even though they can most certainly communicate with each other (and even to us) in various other ways. Although there have been attempts to teach human-like languages to members of other species, none can do so in a way that would easily solve this problem. Instead, it would seem that despite the similarities between our behavior and those of other animals, any such knowledge of their minds would have to be less certain than what seems to be much more immediate knowledge of our own minds. Nonetheless, a strong inductive rationale for animal

consciousness seems sufficient to establish a reasonable belief that most animals have conscious mental states. Sometimes this takes the form of an “argument by analogy” such that, for example, we know how we feel when we exhibit the behavior of someone in fear or in pain and so it seems reasonable to think that the same conscious states are present when a dog or chicken displays the same behavior. This is presumably because we think of such behaviour as *caused by* the relevant conscious state. It is unlikely that we always make such conscious inferences when we observe animal behavior; rather, we probably often simply take it for granted. But this analogical strategy can be found in well-known philosophers throughout history (e.g., Locke, Hume, Mill, and Russell.) One worry about this type of argument is that it seems to generalize from my own single case, which would indeed be a rather weak instance of induction. However, we might instead suppose that it is an argument from *my species* to most individuals of another species (see Perrett 1997). Of course, the details can vary greatly from species to species.

A related line of argument is the so-called inference to the best explanation (IBE) which does not necessarily depend on self-observation. This is because it relies more on the fact that a successful empirical theory sometimes posits the existence of things that are not directly observed (such as electrons) but rather known indirectly by way of their observable effects. In a similar fashion, positing conscious states can be the best explanation of what causes an animal’s observable behavior (Pargetter 1984). IBE (sometimes called “abduction”) is a version of “hypothesis testing” which might be formulated via a “likelihood” principle according to which one hypothesis is favored over another if it alone predicts an observation that would otherwise be unexpected (Sober 2001; see also Allen-Hermanson 2018; Melnyk 1994.)

In any case, what evidence might be used to infer the presence of consciousness in animals? Although many different criteria have been proposed (e.g., Baars 2005; Seth et al. 2005; Edelman et al. 2005), most fall under one or more of the following general headings:

1. Nonverbal or non-vocal behavioral evidence.
2. Ability to use language and/or to communicate.
3. Ability to learn, solve problems, and be creative.
4. Similarity of brain structure to humans.

So, for example, rocks and tables display none of the above criteria and thus we do not think they are conscious. Trees and plants are alive but also do not meet any of the above criteria, for example, they do not jump away or scream when approached with a chainsaw or lawnmower. At the other extreme, humans normally seem to meet all four criteria. However, when we look at the animal kingdom we find that the evidence is often mixed, at least to some extent. Some animals may only meet two or three criteria whereas others might only meet one. What should we make of these cases? At the least, we might suppose that the more criteria met the more likely an animal is conscious even if none of the above criteria is conclusively necessary or sufficient for having conscious states. Of course, it may also depend upon the *degree* to which a given animal can meet a particular criterion.

Generally speaking, with regard to criterion (1), we can point to an animal's behavioral reaction to stimuli or a given bodily movement. If a dog moves in a way similar to me when someone steps on my leg, this seems to be some evidence that the dog is conscious. If mental states cause bodily movements, then it seems reasonable to infer that the mental state (pain, suffering) is present when the typical bodily effect is observed.

With regard to criterion (2), the ability to use language and/or to communicate, we obviously communicate with each other via a common language and thus we take for granted that there is conscious thought behind linguistic utterances. Unlike most philosophers, however, Dennett (1991, 1995) seems supportive of the idea that consciousness requires language in the sense of "story telling" and thus perhaps only humans are conscious. The conscious "self" is really only a kind of narrative that we tell ourselves. But even though many animals cannot linguistically communicate *with us*, it is clear that they communicate

*with each other*, such as in fairly sophisticated whale, chimp, and bird vocalizations. Treating the use of human-like language as a necessary condition for consciousness seems to be an unnecessarily high bar to clear.

With regard to criterion (3), the ability to learn, solve problems, and be creative, the fact that a human student or an animal can learn from a teacher or trainer provides some evidence that they have conscious minds. Conscious working memory and thought seem necessary for at least some kinds of learning. Further, if an animal is able to solve a somewhat novel practical problem, then it seems that at least some primitive conscious thinking is required. Many animals are able to "figure out" what to do when confronted with a challenging or unexpected situation, such as having to make a tool to acquire some food. In some cases, there can even be what appears to be a creative solution to a problem. Humans are clearly also able to be creative in a number of ways. Rocks and trees, on the other extreme, do not learn or solve problems.

Along the same lines, some use "behavioral versatility" or "stimulus independence" as good overall evidence in support of animal consciousness (Griffin and Speck 2004; Newen and Bartels 2007). If, for example, an animal adjusts its behavior appropriately in response to unpredictable challenges, it seems more likely that it is consciously thinking about its situation than when it responds uniformly. Fixed and rigid responses to stimuli seem to indicate a lack of conceptual representation whereas behavioral versatility indicates an ability to think about a given stimulus and act in a much more context-dependent fashion. This sort of capacity seems also to indicate an ability to *learn* from prior experience and to solve problems.

With regard to criterion (4), similarity of brain structure, we might use comparative neurophysiological evidence to help us to determine animal consciousness. A variety of theoretical and empirical arguments have been put forward for the conclusion that consciousness is shared across all mammals. For example, Seth et al. (2005) argue that widespread reentrant activity in the thalamo-cortical complex involve anatomical

systems that are at minimum shared among all mammals and some non-mammals. In addition, many animals share with us some rather primitive areas of the brain, such as the amygdala in the limbic system, responsible for emotions such as fear. This is how discovering specific neural correlates of consciousness in humans might in turn shed light on animal consciousness, especially given our common evolutionary history. To the extent that animals lack some of the brain structures responsible for more sophisticated mental capacities in us (such as the prefrontal cortex), it seems reasonable to suppose that they are not capable of having these kinds of mental states. However, it may also be that some mental capacities are realized in different brain areas in other species (I will return to this line of argument in the section “[More on Some Hard Cases and Brain Structure](#).”).

Of course, for *each* of our four criteria, there always appear to be counterexamples which suggest that the criterion is not *by itself sufficient* for consciousness. Present day robots and machines, just to make this point, are capable of some communication and language use (as well as some appropriate behavioral responses to stimuli). But it is unclear that either suffices for robot consciousness, perhaps partly because there is no common biological history or similarity. Bees, for example, are well-known to communicate to other bees about where honey can be found through a series of rather complicated “dances.” Perhaps bees are conscious but it is at least not as obvious as some other animals. The case is perhaps even weaker for various insects, such as ants, which nonetheless display “avoidance behavior” and some intra-species communication that allow them to survive. Weaker still would be the behavior of bacteria and single-celled organisms where the behavior in question tends to be rigidly fixed. There is also nothing remotely like a “brain” in bacteria and not much of one in some tiny insects. What about creativity? Defining creativity is difficult but someone might suppose that spiders creatively make their rather sophisticated webs even though spider consciousness is at least not that clear. Also, we can program computers to solve chess and mathematical problems but

again this hardly seems to be enough for consciousness.

It may also be that each of the four criteria is not *necessary* for consciousness, depending on unusual circumstances or one’s metaphysical views. For example, someone who is paralyzed and cannot behave or communicate may of course still be conscious. And perhaps some primitive organisms can be conscious without being able to solve problems or be creative at all.

Nonetheless, it seems that one can reach a reasonable inductive inference in favor of consciousness the more criteria that are met (e.g., in higher mammals) and a reasonable inductive inference against consciousness when, say, less than two criteria are met. It is also very important to emphasize that satisfying each criterion can come in very different degrees, for example, compare the behavior of an ape with the behavior of a lizard. Further, the matter can become very complex even within a single type of organism, such as fish (Allen 2013).

In some instances, of course, it may even be difficult to know whether *another human* is conscious, such as in coma cases and in persistent vegetative states (PVS), both of which also raise significant ethical questions (Farah 2008; Braddock 2017). However, the existence of some truly borderline cases does not rule out many other clearer cases of the presence or absence of consciousness.

## Lloyd Morgan’s Canon and Parsimony

Before delving further into some details and specific species, let us pause first to consider an important methodological issue. Much has been made recently over how considerations of “parsimony” or “simplicity” in mental state attributions to animals should be understood. We should of course be careful not to anthropomorphize, on the one hand, but also not to underestimate animal minds, on the other hand. The often quoted Morgan’s Canon says that “in no case may we interpret an action as the outcome of the exercise of a higher psychical faculty, if it can be interpreted as the outcome of the exercise of one which stands

lower in the psychological scale” (Morgan 1894, p. 53). On the surface, the canon seems to favor less-sophisticated mental state attributions or even explanations which only reference the body and behavior of animals under various conditions.

However, many authors have noted serious problems with this notion as well as significant ambiguity in the canon itself (Browne 2004; Allen-Hermanson 2005; Fitzpatrick 2008; Sober 2009, 2012). It is unclear how to interpret Morgan’s Canon and how it relates to the associated notions of “parsimony” or “simplicity.” For example, Browne (2004) explains that Morgan’s Canon is thus not quite the same as following a law of parsimony. He recognizes that “it is parsimonious to explain similar, complex, stimulus-response patterns by similar psychological mechanisms” (Browne 2004, p. 648). So when various animals perform in ways similar to humans on a given task, “it is unparsimonious to adopt one kind of lower-level explanation for the animal’s response on one task and a different kind of lower-level explanation for the animal’s response on [another] task” (Browne 2004, pp. 643–644). Browne thus also seems to have in mind what was discussed in the section “[Animals and the Problem of Other Minds](#),” that is, some kind of reasonable analogical or explanatory notion of simplicity. We ought to attribute mental states to animals (and thus explain their behavior) when they behave similarly to humans under similar conditions.

Michael Tye echoes much of the above sentiment and relies on a kind of argument by analogy as well as the principle of simplicity (Tye 2016, Chapter 5). Citing Newton and Reid, he approvingly borrows the slogan that “similar effects proceed from the same or similar causes.” Indeed, to assign other causes would be to introduce “superfluous causes” and run afoul of something like a principle of simplicity. With respect to animal pain, for example, Tye comments that he is “entitled to infer that the feeling of pain causes [a] behaviour in [animals] too unless I have a *defeater* to that inference, that is, a reason to believe that a causal story is operative in those animals that cannot be reconciled with the causal story that adverts to pain” (2016, p. 75). As we shall see, one potential defeater might be a difference in

neuroanatomy, but Tye ultimately rejects the notion that the lack of neocortex by itself defeats the inference to pain attribution to many animals.

## More on Some Hard Cases and Brain Structure

Aside from the obvious academic interest, there is also the very practical matter of the morality of animal experimentation and eating animals (Singer 1990; Jamieson 2018). At the very least, whether or not an animal can suffer and feel pain should be taken into account with regard to how they ought to be treated. Billions of animals are killed every year for food and used in research. Many of them are subjected to rather cruel conditions. Of course, some think that even if animals are conscious in some basic sense, they still do not deserve moral consideration especially as compared to humans. Few, if any, researchers and meat-eaters doubt that virtually all of these animals can experience pain. Pain, it would seem, is also a fairly primitive conscious state by comparison to most other kinds of mental states (Allen 2004; Shriver 2006, 2018). Still, the function of pain is not merely to avoid bodily damage; it can also have an emotional or motivational element. Thus, there has been significant focus on basic animal sentience in recent years, especially with respect to some of the harder cases, such as fish, crabs, birds, reptiles, cephalopods, and various insects (Tye 2016). Significant discussion of animal neuroanatomy seems particularly relevant to some of the literature, although behavioral responses to stimuli are inevitably also relied upon.

Neurological studies of animal pain often start with the distinction between “nociception” and pain. Nociception is the capacity to sense potentially damaging noxious stimuli and is one of the most primitive sensory capacities. Nocioceptors are linked to nerve endings in the skin, some of which are associated with initially brief and localized sharp pain and others of which result in longer-lasting pain. Neurons functionally specialized for nociception can even be found in invertebrates such as the medical leech and snails.

Since nociceptors are found in such a wide range of species and are even functionally effective in spinally transected animals, their presence in a species provides little justification in inferring conscious pain experiences. Tye explains that in humans “the painfulness of pain in humans is based on activity in two different neural regions: the somatosensory cortex and the ACC [anterior cingulate cortex]” (Tye 2016, p. 79). The ACC is more closely related to the “felt badness” or “unpleasantness” of pain. It seems that when the somatosensory cortex is damaged, what results is still an unpleasant sensation but it is not really described as “pain” as such. We should keep in mind, however, there are abnormal human cases of developmental neuroplasticity (e.g., in hydrocephaly where there is no neocortex) such that conscious states seem to be realized in different than normal neural structures from a very young age. These are indeed abnormal cases of neural plasticity in humans, but they do show that there may be reasons to think that in some animals “the absence of a neocortex does not in and of itself entail that cells homologous to those found in the neocortex are missing too” (Tye 2016, p. 84). Although a lack of neocortex must be taken into account when examining a given creature’s ability to have pains and other conscious states, Tye does not think that it defeats the inference to the presence of felt pain depending upon the extent of behavioral similarity. Interpretation of various experimental results is a matter of ongoing debate with part of the problem having to do with knowing the extent of “neural plasticity” or “multiple realizability” of a given cortical function.

Let us look more closely at some of the harder cases:

Evidence from lesions and brain imaging seems to indicate a key role in human pain for certain cortical structures, especially the anterior cingulate, somatosensory, and insular cortices (Craig 2009). Neuroanatomical factors as well as physiological changes strongly indicate conscious pain in mammals (Shriver 2006) and birds (Calabrese and Woolley 2015). Lesion studies of mammals and birds strongly suggest serious deficits in pain experience (Allen et al. 2005). Even

though there is no neocortex in birds, there are still certain sorts of constituent and ancient neuron cell types found in birds that are found in our neocortex (Tye 2016, pp. 122–125). In addition, behavioral indicators of pain as seen, for example, in farm animals include vocalizations, abnormal postures and limping, and reductions in activity (Prunier et al. 2013). Chicken most certainly actively seek pain relief when forced to live in overcrowded pens and cages. For example, under certain crippling conditions, they choose feed laced with a pain reliever far more often than a feed without it. Under these circumstances, it would seem that avoiding pain suggests that a creature can *feel* pain and thus is capable of at least some conscious states.

There is a very lively debate over fish consciousness and especially about whether fish can experience pain, stress, and suffering (see Rose 2002 and Sneddon et al. 2003 for opposing views). This is particularly relevant in the very practical context of welfare regulation in commercial and sport-fishing. The term “fish” is itself rather ambiguous and does not really correspond to any clear taxonomic group of creatures. There is an incredible diversity and number of fish groups or species, and so it is particularly difficult to make generalizations about fish consciousness (see Braithwaite 2010; Allen 2013; Brown 2015; Tye 2016, Chapter 6, for reviews and extensive treatment). Tuna fish are, for example, closer to us in many ways than they are to sharks, and not all fish are “cold-blooded.”

Nonetheless, a key issue for fish (and reptiles and other animals, for that matter) is the absence of a neocortex (Rose 2002; cf. Rose et al. 2014). Rose (2002) argues that because fish lack the anterior cingulate cortex (ACC), they may not be bothered by pain or merely have (unconscious) nociception. Sneddon et al. (2003) disagree and argue that there is adequate behavioral and physiological evidence for pain in fish (see also Chandroo et al. 2004; Sneddon 2011; Balcombe 2016). Trout, for example, have nociceptors but also respond favorably to painkillers when treated with noxious stimuli and fish react to morphine much as we do. There are numerous articles on fish consciousness in the on-line journal *Animal*

*Sentience*, including Key (2015, 2016) who argues that fish lack the necessary neurocytoarchitecture, microcircuitry, and structural connectivity for the neural processing required for feeling pain. Numerous commentators, such as Broom (2016), Seth (2016), Shriver (2016), and Striedter (2016), reply to Key. Woodruff (2017) reviews neuroanatomical, neurophysiological, and behavioral studies which leads him to the conclusion that fish do have neurobiological correlates and behavioral flexibility of sufficient complexity to support the hypothesis that they are capable of phenomenal consciousness.

Tye (2016, Chapter 6) also argues that fish can feel pain and have other conscious states. He argues at great length that a lack of neocortex is not by itself a defeater for consciousness in various animals. The overall behavior of fish, such as struggling to get away when caught on a hook, is very similar to the way we would behave in such circumstances. And since nociceptors transmit signals that generate pain in humans and other mammals, it seems plausible to suppose that fish feel pain too. Behavioral indications of fear and anxiety in many fish also seem to abound and much the same seems true of basic perceptual consciousness including smell, vision, hearing, and visual discrimination (Tye 2016, pp. 107–113). Once again, the best and simplest explanation of the extensive behavioral similarities between humans and fish, according to Tye, is that fish undergo the same experiences that we do.

A neocortex is also not present in lizards and reptiles, but Cabanac et al. (2009) present some evidence that there is felt pleasure and pain in iguanas. They argue that consciousness is shared by all *amniotes* which include all descendants of the common ancestor of living birds and mammals, such as lizards, snakes, and turtles. Some interesting behavioral indicators of consciousness are also discussed, such as “trade-off” behavior (where, e.g., fish decrease feeding attempts as electric shocks are increased until food deprivation increases), navigational detouring (which requires an animal to pursue a series of non-rewarding intermediate goals in order to obtain an ultimate reward), expression of emotion, expression of sensory pleasure, and emotional

fever (an increase in body temperature in response to a stressful situation). It does indeed often seem rather difficult to explain these behaviors entirely without also attributing consciousness. Reptiles also show spatial cognitive abilities similar to those of rats and exhibit learning or behavioral flexibility in their pursuit of food. Even though reptiles lack a hippocampus as well as a neocortex, there is some reason to suppose that the medial cortex in reptiles operates in a similar way to the hippocampus in mammals (Tye 2016, pp. 131–133).

One intriguing group of invertebrate animals that has received significant attention with respect to consciousness is cephalopods, e.g., octopuses, squids, and cuttlefish. These are clever and large-brained animals who are well-known for incredible abilities to camouflage themselves and for flexible hunting strategies. Mather (2008) argues that cephalopods exhibit many behavioral indicators of consciousness, including complex learning and spatial memory. The octopus is especially interesting. They are highly intelligent, very adept at learning, and display a variety of complex cognitive abilities (Godfrey-Smith 2013). The octopus can even escape from a jar by unscrewing it from the inside. Once again, we must be careful however. Cephalopod neuroanatomy is so very different from mammalian architecture that it may be difficult to be entirely confident in attributions of consciousness. For one thing, over two-thirds of their neurons are located in their tentacles.

Another group of animals garnering significant attention is arthropods, which includes insects, crustaceans, spiders, and many other less familiar animals (Tye 2016, Chapter 8). This is an ancient and diverse group of creatures and so, again, any generalizations should be made with caution. It is interesting, however, to note that arthropods were among the earliest animals to evolve complex active bodies and brains capable of controlling them (Trestman 2013). So, if one function of consciousness is to solve problems which arise due to controlling complex bodies (Merker 2005), consciousness may have evolved very early on among arthropods. The case for insect sentience is sometimes also made on the basis of

neuroanatomical similarity to the mammalian midbrain (Klein and Barron 2016). Klein and Barron argue that basic subjective experience is supported by the integrated midbrain and basal ganglia structures which are among the oldest and most highly conserved brain systems in vertebrates. They argue that the insect brain supports functions analogous to those of the vertebrate midbrain and hence that insects may also have a capacity for subjective experience. (Replies to Klein and Barron can be found in the same 2016 issue of *Animal Sentience*.)

The fact that honeybees recognize faces even from unfamiliar perspectives might be suggestive of mental rotation and visual imagery (Dyer et al. 2005). Jackson and Wilcox (1993) document a variety of impressive behaviors in jumping spiders, including detouring and other forms of apparent planning, as well as flexible, context-sensitive adjustment of predatory behavior to prey behavior. There are numerous studies on bees and, for example, pattern recognition, navigation, communication, visual working memory (Srinivasan 2010), and mood and emotions (Mendl et al. 2011).

Nocioceptors are missing in virtually all insects, but they still do respond to and learn to avoid a range of noxious stimuli, including honeybees. Still, it does seem that a stronger behavioral case can be made against insect consciousness since, for example, they do not move to protect injured body parts in the way that mammals do. Perhaps, however, some of these behaviors can be explained away as attempts to survive in spite of the pain. In the case of bees, there are at least some important physiological similarities and further evidence of intelligence and working memory (Tye 2016, pp. 148–156). As was briefly mentioned in the section “[Animals and the Problem of Other Minds](#),” bees are also well-known for their very sophisticated navigational abilities and intra-species communication via “waggle dances” with respect to the location of food.

Crabs are crustaceans with a highly developed sense of smell but poor vision. Elwood and Appel (2009) seem to show that hermit crabs can remember an aversive event (an electric shock) and can use that memory in later context-sensitive

decision-making (see also Elwood et al. 2009). This seems to be evidence of remembering a painful experience. Crabs also react to analgesics in the same way that honeybees do. If crabs feel pain, then surely bees also do since bees have ten times more neurons than crabs have. Indeed, bee brain *density* is ten times greater than a mammalian cerebral cortex (Tye 2016, pp. 156–158).

In some of the above cases, there are clearly some potential “defeaters” (as Tye calls them) to the conclusion that there really are conscious states in some species. It may indeed even be impossible to infer with any sense of confidence, especially with respect to some insects and crustaceans. Still, as we have seen, there may also be cases where a potential defeater might itself be defeated, such as in some instances where a creature lacks a neocortex. In addition, many kinds of creatures, such as fish and insects, come with an incredible variety of species and so there may be some exceptions which make generalizations difficult to justify.

Feinberg and Mallatt (2016) take a more explicitly evolutionary approach to animal consciousness although some of the same issues raised above are front and center (see also Godfrey-Smith 2018). When did consciousness first appear on Earth and how did it evolve? What constitutes consciousness and which animals are sentient? Using their own list of the neurobiological features that seem responsible for consciousness, Feinberg and Mallatt argue that consciousness appeared much earlier in evolutionary history than is commonly assumed. About 520–560 million years ago, they explain, the great “Cambrian explosion” of animal diversity produced the first complex brains, which were accompanied by the first appearance of consciousness. Simple reflexive behaviors evolved into a unified inner world of subjective experiences. From this they deduce that all vertebrates are and have always been conscious, including fish, reptiles, amphibians, and birds. Considering invertebrates, they find that arthropods (including insects and probably crustaceans) and cephalopods (including the octopus) also meet many of the criteria for consciousness. Part of this still controversial issue is whether or not consciousness

evolved as an adaptive function and then remained as a benefit for organisms (Maley and Piccinini 2018). For example, consciousness may allow organisms to construct an internal model of the world, learn in certain ways, or perform voluntary actions. If this is so, then consciousness confers an adaptive advantage to organisms that have it.

## Animal Consciousness and Higher-Order Thought Theory

It is sometimes alleged that one prominent philosophical theory of consciousness, the higher-order thought (HOT) theory, is inconsistent with animal consciousness (Seager 2004). Indeed, one higher-order theorist has even embraced the normally unwelcome conclusion that most animals do not have conscious states (Carruthers 2000, 2005). Others have responded by defending HOT theory as consistent with most animal consciousness (Gennaro 2009, 2012, Chapter 8).

Let us back up: HOT theory is an example of a so-called representational theory of consciousness which attempt to reduce consciousness to “mental representations” rather than directly to neural states. The notion of “reduction” at work is to explain conscious states by means of non-conscious mental states and thus without reference to consciousness (thereby also avoiding the charge of circularity). Other representational theories include first-order representationalism (FOR) which aim to explain conscious experience primarily in terms of world-directed (or first-order) intentional states (Tye 2000). Higher-order representationalism (HOR) holds that what makes a mental state *M* conscious is that it is the object of some kind of higher-order mental state directed at *M* (Lycan 2001; Rosenthal 2005; Gennaro 2012). There are various kinds of HOR theory with the most common division between higher-order thought (HOT) theories and higher-order perception (HOP) theories. HOT theorists, such as Rosenthal (1997, 2004, 2005) and Gennaro (1996, 2012), think it is better to understand the HOR as a thought containing concepts. HOTs are treated as cognitive states involving

some kind of conceptual component. A HOT is a “meta-psychological” or “metacognitive” state, that is, a mental state directed at another mental state (“I am in mental state *M*”). HOP theorists urge that the HOR is a perceptual state which does not require the conceptual content invoked by HOT theorists (Lycan 1996, 2004).

So HOR theories attempt to reduce consciousness in *mentalistic* terms, such as “thoughts” and “awareness,” rather than directly in neurophysiological terms. Thus, the idea is to reduce consciousness to mental representations. The notion of a “representation” is of course very general and can be applied to pictures and various natural objects, such as the rings inside a tree. Much of what goes on in the brain might also be understood in a representational way. For example, mental events represent outer objects partly because they are caused by such objects in cases of veridical visual perception. Philosophers often call such mental states “intentional states” which have representational content, that is, mental states are “directed at” something such as a thought about a horse or a perception of a tree.

Any theory of consciousness should seek to answer the question: What makes a mental state a *conscious* mental state? The HOT theorist will point out that conscious states, as opposed to unconscious ones, are intuitively mental states that I am “aware of” being in. This overall idea is sometimes referred to as the Transitivity Principle (TP): A conscious state is a state whose subject is, in some way, aware of being in it.

Conversely, the idea that I could be having a conscious state while totally *unaware* of being in that state seems like a contradiction. A mental state of which the subject is completely unaware is clearly an *unconscious* state. For example, I would not be aware of having a subliminal perception and so it is unconscious.

It might seem that HOT theory results in circularity by defining consciousness in terms of HOTs (since HOTs can be thought of as a kind of higher-order “awareness” of mental states, as in TP). It also might seem that an infinite regress results because a conscious mental state must be accompanied by a HOT, which, in turn, must be

accompanied by another HOT *ad infinitum*. However, the widely accepted reply is that when a conscious mental state is a first-order world-directed conscious state, the higher-order thought (HOT) is *not* itself conscious. But when the HOT is itself conscious, there is a yet higher-order (or third-order) thought directed at the second-order state. In this case, we have *introspection* which involves a conscious HOT directed at an inner mental state. When one introspects, one's attention is directed back into one's mind. For example, what makes my desire to write a good chapter a conscious first-order desire is that there is an *unconscious* HOT directed at the desire. In this case, my conscious focus is directed outward at my chapter or computer screen and so I am not consciously aware of having the HOT from the first-person point of view. When I *introspect* that desire, however, I then have a *conscious* HOT (accompanied by a yet higher, third-order, HOT) directed at the desire itself. It is thus crucial to distinguish first-order conscious states (with unconscious HOTs) from introspective states (with conscious HOTs).

In any case, it may seem unlikely that animals (and even infants) have the conceptual sophistication required for HOTs, which would then render animal (and infant) consciousness very unlikely (Seager 2004). Are cats and pigs capable of having complex higher-order thoughts such as "I am in mental state M"?

In reply, however, it may be that HOTs need not be as sophisticated as it might initially appear and, in recent years, some experiments have also strongly suggested that many animals can have metacognitive states. A number of key areas are under continuing investigation including animal memory and uncertainty monitoring. The term "I-thoughts" is also often used in the literature to mean "thoughts about one's own mental states or oneself." Thus, they are very similar to HOTs and closely linked to what psychologists call "metacognition," that is, mental states about mental states, or "cognitions" about other mental representations (Koriat 2007; Beran et al. 2012). Although some still reject the notion that most nonhuman animals have I-thoughts, the evidence seems to be growing that many animals do in fact

have them and may even be able to understand the mental states of others (Terrace and Metcalfe 2005; Hurley and Nudds 2006; DeGrazia 2009).

One area of inquiry has to do with episodic memory (EM) which is an explicitly conscious kind of remembering involving "mental time travel" (Tulving 1983, 2005). It is often contrasted with *semantic* memory, which need only involve knowing that a given fact is true or what a particular object is, and *procedural* memory, whereby memory of various learned skills is retained. Some notion of "I" or self-concept seems necessary to have a genuine EM. I recognize an EM *as mine* and as representing an event in *my* past. To give an example from animal cognition research, Clayton and Dickinson and their colleagues report convincing demonstrations of memory for time in scrub jays (Clayton et al. 2003). Scrub jays are food-caching birds, and when they have food they cannot eat, they hide it and recover it later. Because some of the food is preferred but perishable (such as crickets), it must be eaten within a few days, while other food (such as nuts) is less preferred but does not perish as quickly. In cleverly designed experiments using these facts, scrub jays are shown, even days after caching, to know not only *what* kind of food was *where* but also *when* they had cached it (see also Clayton et al. 2006). Although still somewhat controversial, these experimental results at least seem to show that scrub jays have some episodic memory which involves a sense of self over time. This strongly suggests that the birds have some degree of metacognition with a self-concept (or "I-concept") which can figure into HOTs. Further, many crows and scrub jays return alone to caches they had hidden in the presence of others and recache them in new places (Emery and Clayton 2001). This suggests that they know that *others* know (or at least "see") where the food is cached, and thus, to avoid having their food stolen, they recache the food. This strongly suggests that these birds can even have some mental concepts directed at other minds, which is sometimes called "mindreading." Of course, there are many different experiments aimed at determining the metacognitive abilities of various animals so it can sometimes be difficult to generalize across species.

There is also the much-discussed work on uncertainty monitoring with animals such as monkeys and dolphins (Smith et al. 2003; Smith 2005). For example, a dolphin is trained in a perceptual discrimination task, first learning to identify a particular sound at a fixed frequency (the “sample” sound). The dolphin later learns to match other sounds to the sample sound. When presented with a sound that is either the same or different in pitch as the sample sound, the dolphin has to respond in one way if it is the same pitch (such as by pressing one paddle) and another way if it is a different pitch (pressing another paddle). Eventually the dolphin is introduced into a test environment and forced to make extremely difficult discriminations. To test for the capacity to take advantage of his own uncertainty, the dolphin is presented with a third “uncertain” response, the Escape paddle, which yields a greater reward than an incorrect response but a lesser reward than a correct response. The dolphin chooses the Escape paddle with a similar response pattern to humans and rhesus monkeys which suggest that the dolphin is aware of his state of uncertainty, that is, he has some knowledge of his own mental state. This is clearly a metacognitive state: the dolphin is aware that he does not know something, namely, whether or not a sound matches (or is very close to) the sample sound. Nonetheless, some authors (Carruthers 2008, 2009) argue that these and other experiments do not *force us* to infer the presence of metacognition, but one might respond in a manner similar to the section “Lloyd Morgan’s Canon and Parsimony” above. That is, it is arguably more parsimonious in some circumstances to attribute metacognitive states to animals rather than mere first-order states or no conscious mental states at all accompanied by a far more elaborate explanation of the animal’s behavior (see also Gennaro 2012, Chapter 8, for some discussion).

Some authors (e.g., Carruthers 2000, 2005, 2009) cite experimental work suggesting that, say, even chimps lack the ability to attribute mental states to others (Povinelli 2000). These experiments are designed to determine if chimps take notice of when an experimenter is looking at something (say, food) or is unable to see something (for example, due to blindfolding). Chimps

were just as likely to ask for food from an experimenter with a bucket over her head as from one who could see which seems to indicate a lack of the mental concept “seeing” or “visual perception.” Carruthers further argues that animals with HOTs should also be able to have thoughts about the mental states of *other creatures*. However, it is not at all clear that having I-thoughts *requires* being able to read *other* minds and, in any case, the evidence seems to be growing that many animals can mindread. For example, Laurie Santos and colleagues show that rhesus monkeys attribute visual and auditory perceptions to others in competitive paradigms (Flombaum and Santos 2005; Santos et al. 2006). Rhesus monkeys preferentially attempt to obtain food silently only in those conditions where silence was relevant to obtaining the food undetected. While a human competitor was looking away, monkeys would take grapes from a silent container, thus apparently understanding that their human competitors would hear the noise otherwise. Subjects reliably picked the container that did not alert the experimenter that a grape was being removed. This suggests that monkeys take into account how auditory information can change the cognitive state of the experimenter. As we saw in the section “Lloyd Morgan’s Canon and Parsimony,” parsimony would seem, at least at times, to be on the side of such mental state attributions.

I lack the space here to delve further into this massive literature but for much more on the issue of mindreading and metacognition in animals and infants, see Carruthers (2009), Nichols and Stich (2003), Goldman (2006), Lurz (2011), and Gennaro (2012, Chapters 7 and 8). Goldman (2006) defends the view that self-attribution of mental states (metacognition) is prior to our capacity to attribute mental states to others (mindreading). A more modest view, offered by Nichols and Stich (2003), is that the two capacities are independent and dissociable. Carruthers (2009) argues that mindreading is actually *prior* to metacognition. The two main much discussed views are simulation theory (ST) and theory-theory (TT). ST holds that mindreading involves the ability to imaginatively take the perspective of another. TT holds that metacognition results from

one's "theory of mind" being directed at oneself. Still, many existing theories are in fact hybrids of ST and TT.

Of course, it may be that HOT theory rules out *more* animal consciousness than some other theories, but it arguably does not rule out most animal consciousness. Perhaps insects and crustaceans are *less likely* to be conscious according to HOT theory, but it may depend on some specifics. Not all birds behave in the same sophisticated way that scrub jays do but it seems reasonable to suppose that many other birds are also capable of having at least some HOTs. Other animals mentioned above, such as monkeys and dolphins, are no doubt far more sophisticated than insects. Much the same holds for dogs, lions, pigs, and other mammals. Some of the behavior of, say, bees and fish might arguably even justify the attribution of self-awareness in addition to basic conscious states.

## Conservation

Audrey E. Parrish  
Department of Psychology, The Citadel,  
Charleston, SC, USA

## Synonyms

Constancy; Piagetian conservation; Quantity judgments

## Definition

Conservation, first defined and assessed by Piaget as a critical developmental stage, is the

understanding that the physical qualities of a substance or object (e.g., volume, size, weight, number, quantity) do not change despite a transformation of their physical appearance. Conservation tasks are used to assess logical thinking and inferential abilities in children and nonhuman animals as a contrast to problem solving based on cognitively simpler perceptual strategies.

## Introduction

A hallmark event in cognitive development is the emerging ability to perceive, discriminate, and track quantitative information during childhood, and this capacity has been demonstrated in non-human animals. Conservation tests, first devised by Piaget (Piaget 1941/1997; Piaget and Inhelder 1966/1969), assess a subject's understanding of the constant nature of a substance's quantitative features following a transformation of its physical appearance. This ability requires representation of quantities, such that an individual is able to compare, track, and manipulate stimuli even when those stimuli are visually absent or perceptually transformed. Specifically, a substance's (e.g., liquid or solid) or object set's (e.g., a row of coins) weight, volume, number, size, or quantity is

manipulated in such a way that the transformed stimulus appears to be larger/greater than or smaller/less than it did originally. The objective is for the participant to identify whether the manipulated quantity has remained the same or has changed. In Fig. 1, a liquid (Panel A) and a number (Panel B) conservation task is illustrated. In the top portion of each panel, the quantities are depicted pre-transformation in which participants first identify the quantities as the same or equal. In the bottom portion of each panel, the quantities are depicted post-transformation in which the equal quantities now appear to be different due to the physical transformation (pouring of the first liquid into a new container or separating the bottom row of circles). Successful performance on this task is reflected in the ability to "conserve" a set's true quantity, identifying the quantities as equal despite these misleading physical transformations. Conservation is considered a test of logical or inferential reasoning emerging in the concrete operational stage of development, and children in this stage would understand the constancy of a stimulus despite its physical change in appearance (Piaget 1955).

In the classic liquid conservation paradigm, children are presented with two containers of liquid equal in volume. Once a child acknowledges

**Conservation, Fig. 1** A liquid (Panel A) and a number (Panel B) conservation task is illustrated. In the top portion of each panel, the quantities are depicted pre-transformation in which participants first identify the quantities as being equal. In the bottom portion of each panel, the quantities are depicted post-transformation in which

the quantities now appear to be unequal due to the physical transformation (Panel A - pouring of the first liquid into a thinner, taller container leads this quantity to appear greater in volume or Panel B - separation of the circles in the bottom row leads this quantity to appear greater in number or quantity)

that the liquids are the same or equal, one or both containers are poured into differently-shaped containers (continuous transformation), which cause the liquid(s) to appear greater in volume (if transferred to a thinner, taller container, effectively raising the height of the liquid) or lesser in volume (if transferred to a wider, shorter container, effectively reducing the height of the liquid). Alternatively, one container may be poured into several different containers (discontinuous transformation), which subdivides the liquid into multiple smaller vessels. Children between the ages of 7–8 years old typically understand the constancy of quantities (despite the change in perceptual cues such as liquid volume height), which is indicative of necessary or “true” conservation in line with logical reasoning (Piaget and Inhelder 1941). Younger children demonstrate varying degrees of success in tests of conservation, including a complete absence of conservation (i.e., the belief that the original quantity has changed post-transformation) or intermediary reactions (i.e., conserve following the first transformation, yet reverse choices following subsequent transformations; Piaget and Inhelder 1941).

A growing number of animal species have shown varying degrees of success in tests of conservation using both logical reasoning (indicative of a higher-order cognitive strategy) and perceptual-based strategies (e.g., using the height of liquid volume or pouring rate), which are considered cognitively simpler. In some cases, species’ performances, including those of children, are directly compared using identical stimuli and methodologies for a true comparison of ability. In this chapter, I review the comparative data on conservation and outline how the data fit in line with the original Piagetian framework in developmental psychology.

## Comparative Data

In one of the most widely cited comparative investigations of conservation in an animal species, Woodruff et al. (1978) assessed a female chimpanzee’s (*Pan troglodytes*) understanding of conservation using a same/different paradigm. Previously, the chimpanzee, Sarah, had been

trained to associate two different tokens with the concepts of same and different. For the conservation test, she was presented with two quantities of liquid (water), matter (clay), and discrete items (buttons). At the beginning of a trial, Sarah first attended to two quantities presented on a tray, after which the experimenter manually transformed one of the two substances as she watched. Sarah then responded to the stimuli using the “same” or “different” token. She demonstrated successful conservation of the liquid and matter substances following physical transformations of their quantities. For example, Sarah successfully designated whether the transformed water containers contained a same or different amount of liquid despite the alteration of water height. The matter condition included a change in the shape of the clay so it appeared larger or smaller than the alternative clay, but Sarah successfully designated equal quantities as “same” despite the change in the clay’s appearance. Importantly, Sarah was unsuccessful (i.e., designated the equal quantities as “different”) when she was not shown the quantities before or during the transformation process. This condition was crucial in that Sarah could not have relied upon perceptual cues alone (e.g., liquid volume height) when accurately responding to the conservation trials but rather appeared to use inferential reasoning and an understanding of the invariant nature of quantities to guide responding.

In addition to same/different paradigms, over-conservation tasks are used as a means to study these abilities in children and animals. In this task, subjects are presented with differing quantities (rather than equal quantities) and are trained or instructed to choose the larger of two amounts (Piaget 1968). For example, two juvenile chimpanzees indicated their choice of the larger of two quantities of a high-preference liquid (syrup) by pointing to their desired container (Muncer 1983). This discrimination procedure in which animals simply reach towards their preferred option offers a more spontaneous, prepotent, and arguably more reliable measure of quantity judgment as opposed to one that relies upon symbolic training of same/different concepts. Following the initial choice, quantities were transformed by pouring one of the two liquids into a larger container,

altering the height of the liquid. Muncer (1983) reported that one of the two chimpanzees showed evidence for liquid conservation, continuing to choose the container with the greater volume of liquid, despite being transformed such that it now had a lower height, which could have been misinterpreted as a lesser volume. The same chimpanzee, Jane, also passed a number conservation test in which two rows of candies were manipulated for length (by increasing the distance between each candy); see Fig. 1 as an example. Jane reliably chose the larger number of individual candies post-transformation, despite the larger quantity now appearing as the shorter row. Similar to the results of Woodruff et al. (1978), this chimpanzee failed the test of conservation by choosing the smaller/lesser quantity option if not allowed to examine the containers before and during the transformation procedure, indicating perceptual strategies alone could not account for performance in the critical test trials.

Following the Muncer (1983) study, several primate studies utilized the overconservation paradigm. Call and Rochat (1996) directly compared orangutans (*Pongo pygmaeus*) to 6–8-year-old children on a series of nearly identical conservation tasks. Orangutans were first trained to choose the larger quantity of preferred liquid (juice) presented in identical transparent containers via pointing which led to its immediate delivery for consumption. Children were not allowed to drink the chosen liquids but were instead instructed to choose the container under the assumption that they were “very, very thirsty” to promote maximization. In conservation test trials, Call and Rochat varied task difficulty by manipulating container shape and the type of transformation (continuous or discontinuous). They also ruled out the use of perceptual cues such as pouring duration, the sound of liquids being poured, and the flow or speed with which liquids were transferred to negate the use of these simpler strategies in solving the task. Most orangutans (three of four) performed well in the continuous conservation test, in which one of two containers of liquid was poured into a single differently shaped cup. When quantities were occluded during the transformation procedure, performance fell to chance

indicating that orangutans did not rely upon non-visual information such as pouring duration or auditory pouring cues. However, orangutans did not pass a discontinuous transformation experiment in which a container was subdivided into multiple smaller containers. In this experiment, some orangutans preferred a single cup with a higher liquid height whereas others preferred the greater number of individual cups or a combination of strategies. Thus, the Call and Rochat argued for “pseudo-conservation,” with the orangutans maximizing juice intake following relatively simple transformations of physical appearance. Interestingly, only two of 10 children succeeded in all experiments demonstrating evidence of true conservation according to Piaget and Inhelder (1941). All remaining children showed varying degrees of success across experiments, with evidence for intermediary reactions to conservation. These developmental results highlight the importance of also reporting individual differences among human subjects to shed light on the ubiquity (or not) of certain cognitive processes. We also must consider whether only one, a majority, or all individuals of a given species must “pass” a test for the results to be considered as significant, and whether those standards should be different for humans and nonhuman animals.

In a series of experiments, Suda and Call investigated conservation performance in chimpanzees, orangutans, and bonobos (*Pan paniscus*) with a specific focus on the strategy used to resolve a variety of transformations and to expand the number of individuals and species represented in this work. In the first study assessing liquid conservation, Suda and Call (2004) reported varying degrees of success within the great apes in their ability to conserve quantities of liquid across a number of transformations using differing container shapes and types. The apes appeared to most heavily rely upon visual information regarding liquid volume which depended on container shape, leading to incorrect selections of the smaller quantity because of its altered appearance. Further, the apes’ performances were disrupted to some degree when liquids were transferred to opaque cups, confirming the apes’ use of perceptual strategies (i.e., visually estimating the final

height of the liquid) to guide choice behavior. These results are consistent with previous studies of orangutan conservation performance (Call and Rochat 1997) and more recent data examining chimpanzees' responses to quantitative illusions, in which choice behavior in a series of quantity discrimination tasks was disrupted by contextual cues. Chimpanzees preferred equal and even smaller quantities of foods (both liquid quantities and quantities of discrete food items such as cereal) when presented in a container that caused the food to appear fuller or larger in size than its equivalent or perhaps truly larger counterpart (Parrish and Beran 2014a, b). Suda and Call reported that the apes were more successful when they were allowed to view the transformation process (e.g., visibly see the liquids being poured into different containers), although responding was partially guided by the use of perceptual estimation as well. These same authors discussed the role of cognitive conflict for apes that performed to intermediate levels of success (neither highly successful or unsuccessful; Suda and Call 2006). The mid-level performing apes displayed the highest degree of hesitancy in their choices (measured in terms of selection changes and simultaneous points to both quantities), which is perhaps indicative of greater cognitive conflict in reconciling how a liquid appears post-transformation versus what a liquid quantity truly is despite its appearance.

In a subsequent study, Suda and Call (2005) investigated the role of continuous (liquid) and discrete (itemized) quantities on conservation performance. Discrete quantities (for example, cereal pieces) presumably are easier to conserve than continuous quantities because although the spatial layout of the individual items is altered, the individual stimuli themselves remain constant (Peisach and Hardeman 1975). Developmental work supports this hypothesis that discrete stimuli are easier to conserve, including evidence for earlier success in number conservation tests (using items such as buttons) in younger children in comparison to liquid or solid conservation that appear later in development (e.g., Brainerd and Brainerd 1972; Gruen and Vore 1972; Samuel and Bryant 1984). Suda and Call (2005) directly pitted

continuous versus discrete conservation abilities of bonobos, chimpanzees, and orangutans to test whether this same pattern of performance held true nonhuman primates. Bonobos (but not chimpanzees and orangutans) performed better in tests of number conservation (using discrete edible stimuli – raisins) versus liquid conservation tests (juice). The authors reasoned that this performance pattern possibly was due to a more astute ability to estimate numerical versus liquid quantities and an overall greater level of experience with discrete foods versus continuous liquids on a daily basis. More convincing though, was the apparent difference in motivational state to obtain the discrete food items between species. The raisins used as the discrete stimuli were seemingly less preferred than the continuous stimulus (juice) by the chimpanzees than bonobos, which may have led to an overall lower motivational state to obtain the largest number of discrete items for chimpanzees. Future studies assessing the role of motivation in conservation performance is therefore needed. The orangutans in Suda and Call (2005) again outperformed the *Pan* species with near ceiling levels of performance in both liquid and number conservation tests, although these studies involved relatively low numbers of subjects.

In another study of chimpanzee quantity discrimination and conservation, Beran (2010) presented chimpanzees with a two-choice discrimination procedure comparing sets of liquid juice. Conservation of liquid quantities was tested by transferring one or both liquid sets into transparent or opaque containers via syringe. Consistent with their ability to discriminate discrete quantities according to the ratio between sets (e.g., Beran 2001, 2004; Hanus and Call 2007; Rumbaugh et al. 1987), chimpanzees excelled in their discrimination of continuous quantities regardless of whether both sets were visible (transparent containers) or whether one or both sets were non-visible (opaque containers). Relevant to conservation abilities, their performance was not reliant upon auditory or visual cues of liquid transfer as success rates remained high despite variations to the pouring height/rate during the transformation process. Beran reports that the success in conservation performance was

accounted for via tracking of liquid quantities as well as a perceptual strategy of estimating visual information of liquid height when sets were visible.

Other studies have extended conservation tasks to non-ape species including capuchin monkeys (*Sapajus apella*), a particularly interesting species in that they share a number of cognitive processes in common with Old World monkeys and great apes including self-control, numerical cognition, concept formation, spatial representations, and analogical reasoning (e.g., D'Amato and Colombo 1988; Flemming 2011; Kennedy and Frigaszy 2008; Wright and Katz 2006). With regard to number conservation tests, Beran (2008) demonstrated that capuchin monkeys could respond to transformations of discrete item sets presented on a computer screen. Monkeys first were trained to select the larger of two digital arrays of squares onscreen by contacting the more numerous set via joystick-controlled cursor. In test trials, after their first selection, the spatial layout of one array was manipulated to comprise a larger or smaller area by spreading out or compressing the array, a manipulation that did not actually change either quantity. Or, additional squares were added to one array, which did change the relative quantity judgment. Importantly, non-quantitative cues, such as the overall surface area of the array as well as whether the smaller or larger array was manipulated, were controlled so that the monkeys had to rely on true quantitative information to guide responding. Capuchin monkeys succeeded in this task, reliably selecting the larger of the two arrays following spatial transformations and additions to one of the two sets. These results closely aligned with data from a separate experiment assessing number conservation in rhesus macaques (*Macaca mulatta*) by Beran (2007), and both studies were key to expanding the comparative data set beyond the great apes to incorporate more phylogenetically distant primates.

In a more recent study, Pepperberg and colleagues extended conservation testing to four African grey parrots to include a non-primate in this area of research (*Psittacus erithacus*; Pepperberg et al. 2017). The researchers first

demonstrated the ability of parrots to choose between two different amounts of liquid presented in identical containers, an important precursor to testing conservation abilities. Three of the four birds reliably chose the larger quantity of liquid. The one chick that initially failed (approximately 6 months old) subsequently passed this initial testing at approximately 9 months old. This age-related change in performance demonstrates a development in quantity discrimination abilities and/or improved attention to the task. In the conservation tests, liquid quantities were either visibly (in full view) or invisibly (out of view) transferred to new containers. In invisible transformations, parrots used a perceptual strategy, selecting the container that would normally appear fuller despite being equal in amount to the alternative container. These results stand in contrast to visible transformations, in which the parrots responded on the basis of inference, seemingly understanding the invariance of liquid quantities. In these trials, they showed no preference for the equal quantities despite their change in physical appearance due to container shape. These results are consistent with earlier studies of great ape performance in conservation tasks utilizing both visible and non-visible transformation processes (e.g., Muncer 1983; Woodruff et al. 1978).

## Summary

The ability to conserve quantitative information following physical transformations (and changes in perceptual cues of quantity such as liquid volume height) is a hallmark of cognitive development within young children. Comparative research of quantity conservation suggests that an increasing number of species understand the invariance of liquid and solid quantities to some degree. Researchers have systematically assessed a variety of perceptual and decisional strategies that could account for animals' performances and demonstrate a form of pseudo-conservation that allows for the conservation of quantities through relatively simple transformations. Often, these studies have shown that animals will rely on

perceptual estimation abilities (e.g., visually inspecting the height of the transformed liquids) or may only conserve quantities through one transformation (continuous conservation) but fail tests presenting multiple transformations (discontinuous conservation). A reliance on these simpler strategies or intermediary performance suggests that an animal, or a species, has not achieved the level of “true” or necessary conservation as originally defined by Piaget and Inhelder (1941) and as demonstrated in the concrete operational stage of development (7–8 years of age). However, these perceptual strategies cannot account for all data as a number of studies have demonstrated successful conservation only when animals are allowed to inspect quantities prior to and during the transformation process (ruling out simpler strategies) as well as various experimental manipulations that rule out the use of perceptual or non-quantitative cues.

Comparative studies have assessed a number of primate species, including children, great apes, Old World and New World primate species, and most recently an avian species. A broader assessment of conservation abilities across species is needed to build a more complete phylogenetic map than we currently have. Direct comparisons using identical stimuli and methodologies are key to this development, while also balancing species-specific variables including variance in motivational and attentional states as well as quantity discrimination and perceptual abilities. Furthermore, comparisons of performance on conservation tasks to other tests of logical reasoning (e.g., other Piagetian tests) should be undertaken to help us understand better whether these cognitive abilities translate to problem solving and logical thinking outside of the quantitative domain within these same individuals and species.

## Consistent Behavioral Variation

### ► Coping Style

## Consolation

### ► Post-conflict Affiliation

## Consort

Adeelia S. Goffe

German Primate Center, Göttingen, Germany

## Synonyms

Marriage; Pair bond

## Definition

To consort is to engage in a heterosexual pairing for the purpose of sexually reproducing offspring. This behavior requires the maintenance of spatial associations and some level of cooperation and coordinated behavior between paired individuals, along with spatial tolerance and the occurrence of social exchanges. Consortships are initiated by signals or displays that advertise availability and quality of potential mates. Consort pairings are observed across a variety of vertebrate and invertebrate taxa and the methods by which individuals choose and compete for potential partners varies.

## The Function, Forms and Frailties of Consort Behavior

Several factors, such as interindividual distances, population density, female sexual synchrony, and the length of female estrus, dictate when and with whom heterosexual consortships may occur. Comparatively large geographic distances due to solitary foraging behavior can serve as a challenge for potential partners to locate each other. Often, this is mediated using auditory or chemical signals to allow for heterosexual pairs

of conspecifics to come together prior to ovulation in order to mate and reproduce. To minimize the loss of reproductive opportunity, consortships in solitary living *Mustela putorius* include repeated copulations to induce female ovulation (Lodé 2011). On the other hand, potential consort partners in *Poecilia reticulata* come together in groups and engage in ritualized courtship to choose among or compete for consort partners (Kodrie-Brown 1993).

As the timing of consortships is centered around reproductions, secondary sexual characteristics in group living animals have evolved in some species to signal sexual receptivity and allow males to loosely identify the timing of ovulation. For example, in some Old World primates and apes, morphological changes in the sexual skin of females loosely reflect underlying endocrinological fluctuations, which, tied with behavioral signals, allow males to loosely determine the timing of the follicular phase (Campbell et al. 2011). Although copulations may be observed prior to or post-ovulation, mating behavior peaks around the time of maximal tumescence of the sexual skin, which serves as a graded signal to males (Campbell et al. 2011).

Over a given reproductive period, consort pairings may vary in their duration and their number due to fluctuations in partner choice, coercion, or competition. In *Macaca sylvanus*, individuals mate promiscuously within short-term consortships, which may last for several minutes or hours, and males do not use overt coercion to control female mating behavior (Campbell et al. 2011). In other species, male dominance relationships (attained through competition) and various degrees of coercion of females may influence a male's sexual access to females and the likelihood of a male being the consort during a conceptive cycle (Connor and Vollmer 2009). Females may try to resist, but in sexually dimorphic species, such as chimpanzees, dolphins, and orangutans (Connor and Vollmer 2009; Knott et al. 2010), males may have the physical advantage. In other instances where male competition is high and the number of receptive females is low, males may need to form coalitions with other males to

successfully consort with females (Connor and Vollmer 2009).

Mating systems do not necessarily correspond with the success of a consortship. In species that practice long-term monogamy, such as the black vulture, cheating is rare; thus, extra-pair paternity is low, and there is a strong overlap between the social and genetic mating system (Decker et al. 1993). However, within the bounds of well-established socially monogamous pairings, extra-pair copulations may in fact be common. Of the bird species studied, Griffith et al. (2002) found that 90% engaged in extra-pair copulations, indicating a significant discontinuity between the social and genetic mating systems of many socially monogamous birds.

Long-term consortships are facilitated by complex behavioral interactions that vary in the range of behaviors displayed and the contexts in which they occur. These relationships are characterized by strong social and spatial preferences and are mediated through neuroendocrine pathways. For example, Carter et al. (1999) describe the interplay of hormones and behavior in *Microtus ochrogaster*. Following 24 h of mating during which the female comes into estrus as the result of elevated estrogen levels, the pair bond forms between the male and female as concentrations of oxytocin, vasopressin, and corticosterone shift in the two sexes. In males, corticosterone and vasopressin increase, facilitating male-male aggression and pair bonding. In females, elevated stress levels (which can be brought on by the presence of stranger males) result in decreased fertility. Therefore, by sequestering females, via mate guarding, *M. ochrogaster* males facilitate female ovulation (via elevated estrogen levels) and allow for the formation of a pair bond (via elevated oxytocin levels) in females.

Consortships serve to provide direct fitness benefit to participants through the sexually reproduction of offspring. In some species, this requires a small degree of behavioral coordination between individuals and a short-term investment of reproductive material (e.g., Lodé 2011). However, in other cases one parent may not be sufficient to successfully raise offspring, and previous consort partners may be needed to contribute to

the care of dependent offspring. For example, in savannah baboons, a male who consorted with a female during her previous conceptive cycle may care for his potential offspring and provide social protection for mothers (Seyfarth and Cheney 2012).

In addition, when consortships require dispersal outside of the group, they may also provide indirect benefits to participants through intragroup alliances. Human “marriage” serves a sociopolitical role by creating and maintaining alliances across social units while also having socioeconomic implications through the acquisition of transmission and acquisition of resources (Thornhill 1991).

## Conspecifics

Daiani Kochhann  
Center of Agrarian and Biological Sciences, State University of the Acaraú Valley, Sobral, Ceará, Brazil

## Definition

Organisms belonging to the same species.

## Introduction

Conspecifics are all organisms belonging to the same species. In most species, conspecifics will be the ones that individuals interact most. The variability of interactions between conspecifics will vary a lot among animals, depending most on the reproductive characteristics and social structure of the species. Social structure varies from nonsocial or solitary animals, that spend most of the time without interacting with other members of their species, to the different degrees of social animals, that interacts almost all the time with conspecifics (Wcislo and Danforth 1997).

## Communication

The first step in conspecific interactions is the evolution of communication mechanisms. Communication between conspecifics is observed in many aspects of animal's life. The most basic communication must be the one involved in reproductive behavior. Male and female of the same species must communicate to: (1) analyze receptivity and fertility, (2) assess quality of their partner, and (3) species recognition (Keller-Costa et al. 2015). Conspecific communication also involves alarm calls or cues that signalize a risk of predation, evoking antipredator behavior of the conspecifics around (Kaplan 2014). Avoiding serious conflict is also acquired through conspecific communication (Arakawa et al. 2011; Kaplan 2014; Keller-Costa et al. 2015), as well as informing about food availability (Kaplan 2014) and health status of individuals (Arakawa et al. 2011). All this information (and much more) is transmitted between conspecifics using olfactory, visual, and auditory cues that are sent from one conspecific to another.

## Learning from Conspecifics

As conspecifics almost ever have a closer relationship, it is expected that individuals can learn from each other. This is especially true for most social species. Learning from conspecifics can

be observed in a variety of areas and species. Just as examples, individuals can learn about predators and predation risk (e.g., in tadpoles, *Lithobates sylvaticus*; Lucon-Xiccato et al. 2016); how to vocalize (e.g., in the zebra finch, *Taeniopygia guttata*; Jesse and Riebel 2012); and how to increase their foraging skill (e.g., in wild brown capuchins, *Cebus paella*; Gunst et al. 2007). As learning is mediated by communication, it will also use olfactory, visual, and auditory cues.

## Conclusion

Conspecifics are all the organisms belonging to the same species that interact most during their life. Interactions will be mediated by communication, and a variability of cues evolved to facilitate these interactions.

## Constraints on Learning

Robert Ian Bowers  
School of Psychology, University of Minho,  
Braga, Portugal

### Definition

“Constraints on learning” refers to violations of the generality of learning. The same scope of phenomena may be referred to positively as the specificities of learning, but it is worth remembering the negative “constraints” phrasing due to its cautionary history. The phrase “biological constraints” is often used with the same scope, but this loads an interpretation regarding what is producing an effect, and this loading is furthermore ambiguous, referring to evolutionary factors to some writers, but physiological factors to others. Alternatively, the qualifier “biological” may be intended to restrict the scope to factors related to

the organism (i.e., biotic factors), but “biotic” is insufficiently restrictive, including species- and system-general constraints, such as effects related to stimulus novelty or intensity.

### Background

Early learning researchers (e.g., W.S. Small, L.W. Kline, and J.B. Watson) stressed attention to the specificities of the animal studied, and the importance of incorporating such knowledge into the study of animal learning. Moved by pressures of repeatability and isolation of measurable variables, the pioneers exploited such specificities in developing apparatus and procedures; their successes in doing so testifies to the keenness of their observations of these specificities (Timberlake 1983). This acute awareness of the specificities of their animals waned over the following decades, perhaps because later generations of scientists inherited developed apparatus and modus operandi, and the reasons these worked so well were not in the reports. The general aspects of learning proved more memorable than the peculiarities. The field progressively embraced claims of “equipotentiality,” that the cues, responses, and reinforcers involved in a given learning circumstance are arbitrary, and can be treated similarly to any other cue, response, or reinforcer, respectively (attributable to I.P. Pavlov). Optimism in the generality of learning soared, and diversity of species and processes studied plummeted (Beach 1950). These developments yielded confidence in abstract terms of description, which provided the context for a boom in learning research and theory.

John Garcia and colleagues (e.g. Garcia et al. 1955) made a splash with their work on taste aversion learning. This was a striking example of specificity of learning, in which an animal learns to avoid novel tastes that have preceded even a single instance of nausea, even when separated by very long delays. In one demonstration, rats were presented with an audiovisual stimulus whenever they drank the saccharine-tainted water provided (Garcia and Koelling 1966). Subjects made nauseous by radiation developed aversions

specifically to the taste, whereas another group of subjects presented with foot shock selectively developed aversion to the audiovisual cue. Learning was selective. This selectivity, together with their earlier demonstrations that taste aversion learning occurred after a single pairing, and with long delays, challenged the generality of the apparent laws of learning. Although violations of equipotentiality had spattered the literature throughout the history of animal learning research, discussions of such results had tended to be peripheral. Garcia put the specificities in focus. For a variety of reasons, including some valid (perhaps overzealous; Garcia 1981) methodological concerns, doubts about whether the challenged views were indeed committed to equipotentiality, and perhaps some disciplinary conservatism (Garcia 1981), Garcia's message was initially received with resistance among some learning psychologists. Meanwhile, it was touted by others, and ultimately had great impact.

Throughout the 1960s and 1970s, the apparent generalities of learning became progressively spotted with exceptions. As the evidence mounted, it became hard to deny that the abstract principles of learning require qualification. Learning is constrained (Breland and Breland 1961; Hinde 1973; Shettleworth 1972). Typical general-process theories of learning provide no means for predicting such exceptions. There were two general reactions to this.

One reaction was to rework a general-process theory to better account for the exceptions. This strategy had been taken to account for specificities in learning models for decades, encouraged by the staunchly data-driven attitudes toward theory building prevalent at that time, particularly endorsed by K.W. Spence and W.K. Estes. This approach treats specificities as theoretically mundane, reflecting variables such as sensory or motor capacities, rather than learning per se. Learning models typically include learning rate parameters to allow for differences among stimuli in their potential to support conditioning, for example, due to salience of the cue, which will vary across species with different sensory apparatus. One problem with this approach is that such models

have no way of discerning sensory specificities from learning specificities, with all of the between-species variability hidden in the same parameters. In similar fashion, selective association effects (e.g., Garcia and Koelling 1966) could be accommodated by positing a "belongingness" principle. Such attempts to assimilate exceptions into a general-process approach continued to permit models to fit much of the available data, but elegance waned as exceptions mounted. This approach was criticized as conservative, glossing over constraints atheoretically, and appearing to save general process views of learning by absorbing exceptions into empirically tweaked parameters and provisos (Domjan and Galef 1983).

## Turning to Evolution

The other major reaction to the appearance of exceptions in the principles of learning was to turn to evolution. Widespread agreement developed that adopting the methods of biology for the study of learning held promise. However, a principled biological approach to learning proved elusive. Several attempts have been made to apply biological methods to the study of learning, with varying degrees of success. Such attempts fall roughly in three categories.

### Preparedness

One such attempt was to consider animals as predisposed or "evolutionarily prepared" (Seligman 1970) to learn about certain stimuli more readily than others. Exceptions to general laws of learning were attributed to predispositions to learn certain responses, in certain ways, with certain stimuli, in certain circumstances, that accorded with functional expectations.

This approach was dissatisfying for a number of reasons. First, this was not the paradigm shift it superficially appeared to be. Constraints were not being used to question the basis of the general process learning approach as much as to save it, using evolution to explain why there were exceptions, and treating them as such. It was again conservative; general-process approaches

could proceed as they had, just footnoted to admit occasional evolutionary anomalies (Shettleworth 1972; Domjan and Galef 1983). Second, it is unproductive. Beyond just that there are predispositions in learning, the empirical point that motivates talk of preparedness, this starting point turns out to be its only prediction, leaving it theoretically vacuous. If preparedness is defined in terms of the amount of training required to acquire an association (Seligman 1970), attempts to explain the ease of acquisition as preparedness is circular. Third, it does not give positive terms for theory to build upon. Treating constraints as exceptions explicitly denies a common explanatory framework. If various specificities share common features, this perspective gives no theoretical guidance in identifying them. This includes mechanistic bases, leaving specific learning phenomena outside of the explanatory scope of a mechanistic analysis.

Alas, this was not adoption of a principled evolutionary approach. Although it admits selectivity of learning, its appeal to evolution for explanation is post hoc. Although much of the “biological constraints” research was aimed at questioning a general process view of learning, and so not wholly atheoretical, such work generally did not have a coherent positive message concerning specificity of learning. Such research did not generate real theoretical alternatives to a general-process view of learning. Exceptions to general-process views of learning continued to be treated as exceptions. Missing was a general understanding of the newly documented breadth of learning phenomena.

### Specific-Process Approaches

Much research on learning has taken a more genuinely ethological orientation, beginning with specific-process assumptions, and treating specific learning phenomena as specific adaptations, situated in specific ecological contexts, with attention to their functional significance, and specific selection pressures. Some forms of learning have consistently been studied by this approach, such as imprinting (e.g., Lorenz 1937) and mate-choice copying (e.g. Bowers et al. 2012), while others,

such as food conditioning paradigms, have typically been approached in general-process terms. Shettleworth (1972) advocated embracing the diversity of learning, in line with an earlier recommendation of Beach (1950), and approach learning as a “multiplicity of principles.” This approach is closer to the evolutionary orientation several animal learning researchers had been advocating, and is a precursor for a principled comparative study of learning (Domjan and Galef 1983).

A biological orientation is well suited for answering some kinds of questions, but not others. Adoption of functional terms of description is only a first step toward principled application of biological methods. Although comparative methods have been applied with success (e.g., Timberlake and Washburne 1989), the literatures of at least some kinds of learning show no clear relationships with ecology or phylogeny (e.g., Bowers et al. 2012), without which comparison loses force, and the perspective loses one of its strongest methods. Approaching learning phenomena as specific adaptations embraces the diversity of learning, but does not provide answers for many questions regarding what is special about a given manner of learning, and provides no basis for a general mechanistic understanding of that diversity.

### Integrative Approaches

Several thinkers have developed hybrid strategies for retaining the benefits of specific-process approaches in ways that specifically suit the study of learning. These include Ecological Learning Theory (Davey 1989), Releaser-Induced Recognition Learning theory (Suboski 1990), and behavior systems approaches. Among these, Behavior Systems Theory (Timberlake 1983) has had the greatest impact on contemporary views of learning, providing a general framework for interpreting species- and system-specific learning phenomena that had appeared awkward for older views of learning. The principal intuition is in viewing the unconditional in terms of structured motivational systems and interrelated response forms, as opposed to discrete stimuli and responses.

## Summary: Changing Perspectives on Constraints

Describing specificities of learning as “constraints” expresses the matter negatively, as a failure of general-process assumptions, implicitly endorsing a general-process default view. An early learning researcher can scarcely be blamed for stressing generalities over peculiarities. The existence of a general-process description of a phenomenon, however, is no justification for the exaggerated faith in equipotentiality claims that followed. An abstract analysis was confused for a fact about the natural world. The mistake of “constraints” research was taking a general-process approach even to the specificities, which rather warrant a specific-process approach. However, a principled specific-process approach suited to the study of learning proved harder than apprehended, and required development of integrative approaches, a lesson that the allied fields concerned with animal learning are still slowly but surely coming to terms with.

Max-Planck Comparative Cognition Research  
Group, Tenerife, Spain

### Definition

Contact calls are calls that are given toward conspecifics with affiliative bonds, such as mating partners or group members. Contact calls contain various social information that is used to maintain cohesion or movement coordination and for identity advertisement.

### Introduction

Contact calls are widespread in social mammals and birds and play an essential role in mediating social interactions (Rendall et al. 2000). This role includes establishing new social bonds, affirming existing connections, or maintaining cohesion and coordinating movement among group members (Marler 2004). Contact calls are often used in the absence of visual contact, for example, when distance or surroundings restrict visibility or when visual communication with specific individuals is limited due to crowded groups. Among their functions, contact calls can be used to locate and assemble group members, recruit new members to temporary aggregations, and coordinate group position and movement for shared activities such as foraging and roosting. Contact calls can range from soft sounds to screams, depending on whether socializing animals are close together or far apart (Sugiura 2007). One of the most striking characteristics of the contact calls is that they may provide information about the identity or social affiliation of the caller (Cortopassi and Bradbury 2006). It has been assumed that the amount and type of identity

information provided by contact calls might be linked to the social organization (Kondo and Watanabe 2009). For example, socially stable species often converge on shared group-specific contact calls (Cortopassi and Bradbury 2006), while in socially fluid species, contact calls tend to be individually distinctive (Tyack 2003). Such individually unique contact calls may function as individual signatures. Signature contact calls (or whistles) have been found in primates, dolphins, parrots, and corvids suggesting that they may be essential for referential communication in societies with high fission-fusion dynamics (Kondo and Watanabe 2009).

### Types of Information

Several studies in birds and mammals have revealed that contact calls possess acoustic individuality that can be used for individual recognition (Kondo and Watanabe 2009). According to the social relationships associated with individually distinctive calls, individual recognition can be classified into three categories: mates, kin, and group members.

Mate recognition has been found mainly in group-living monogamous bird species, such as passerines (Vignal et al. 2004) and parrots (Wanker et al. 1998), showing both individual differences in contact calls and selective response to mates' contact calls. In contrast, mate recognition using contact calls is rare in mammals, in which monogamy is not a prevalent mating system. Contact calls are also involved in kin recognition such as parent-offspring vocal recognition and have been found in cooperatively breeding birds and mammals (for a review see Kondo and Watanabe 2009). Finally, individual recognition beyond such fixed social relationships is also required for animals that live in complex societies with fission-fusion dynamics in which group composition and social relations change in space and time and has been documented in a variety of species living in such complex societies ranging from primate to dolphins and birds (Kondo and Watanabe 2009).

## Conclusions

Contact calls have been traditionally thought to have comparable functions among animals with different social organization. However, previous studies on various birds and mammals provide evidence for different emphases of contact-call functions depending on the species' social structure. Animals living in stable social groups might use contact calls mainly for group cohesion, whereas animals living in fluid fission-fusion societies might use contact calls to advertise identity. Future studies that take into account the diversity of complex social systems are needed to understand the evolution of contact calls and their function in birds and mammals concerning the socioecological background.

## Contact Comfort

Vanessa Bonetti

Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD),  
Poolesville, MD, USA

## Definition

Contact comfort is defined as the physical and emotional comfort an infant receives from being in physical contact with the mother or caregiver.

## Introduction

Contact comfort was first explored by Harry Harlow in 1958, researching affectional variables (Harlow 1958). He placed neonatal and infant macaque monkeys with two surrogate “mothers”: one that was only made of wire and provided food with a baby bottle and another that was covered in terrycloth and provided warmth and comfort, but no food. The baby monkeys spent most their time with the terrycloth mother and only went to the wire mother when they were hungry. Harlow

concluded that contact comfort is a very important variable in developing an infant's affection to its mother, and lactation is a variable of insignificant importance (Suomi and Kolb 2017). This entry summarizes the current knowledge about contact comfort, the studies that have been executed to examine this phenomenon, and most recent applications to human health and well-being.

### Contact Comfort as a Safety Net

Harlow studied how fear-producing stimuli and curiosity-manipulatory stimuli affected differential responsiveness to both types of surrogate mothers. The monkey infants were presented with various fear-producing stimuli, while in the presence of both surrogate mothers, and he recorded their differential responsiveness to each mother. Infants highly preferred the cloth mother over the wire mother, and with age and experience, this differential selectivity increased.

When examining exploration, stimuli that evoked curiosity-manipulatory responses were placed in a strange environment, and infants were placed in this situation with no surrogate mother in one session, and the cloth mother in the next session. In the presence of the surrogate mother, after a few sessions the infants became comfortable to explore the stimuli, return to the mother for comfort and then return to explore the strange environment and its stimuli again. When the surrogate mother was absent, the infants exhibited emotionality and anxious behaviors, with little exploration.

These studies illustrate the importance of a mother figure who provides comfort to infants, allowing them to explore the environment and reducing their stress level during anxious and fearful situations.

### From Harlow's Contact Comfort, to Bowlby's Attachment Theory

Observing how animal species are attached to a caregiver that provides comfort led to Mary Ainsworth exploring how human infants attach and

bond with their caregivers. Based on John Bowlby's attachment theory, which states that humans and other species are primed to become attached to a mother figure, Ainsworth (1979) developed a testing scenario called the "strange situation" experiment. In this experiment, a human infant is observed while its mother is present, separates from the infant, and then reunites with the infant. Ainsworth found that there are four types of attachment classifications; secure, avoidant, anxious, and disorganized attachment. In the general population, 55% of infants have a secure attachment, 23% have an avoidant attachment, 8% have an anxious attachment, and 15% have a disorganized attachment (Benoit 2004). These attachment styles become developed with early mother-infant interactions. Healthy, secure attachments establish from mothers that were more sensitively responsive to infant signals, than mothers who ignored their babies or were more rejecting, angry, or restricting to their infants.

With evidence that contact comfort and caregivers providing sensitive and loving care leads to a secure bonding attachment style for the infant, it is important for caregivers to be taught to provide contact comfort and not neglect the signals and emotions that infants display.

### Reducing Pain and Stress in Human Newborns

Studies of contact comfort have also influenced the development of skin-to-skin contact (SSC), defined as the placing of the newborn onto the mothers' chest, which has great benefits to human newborns by reducing pain and stress. When testing whether skin-to-skin contact reduced experienced pain of infants during a heel lance versus a control condition, researchers found that crying was reduced by 82%, and grimacing by 65% (Gray et al. 2000). It was also found that newborns in the contact group had a stable heart rate throughout the study, compared to the newborns in the control group who had a quick heart rate rise during the recovery period, illustrating the induced physiological response to pain from the heel lance.

To explain why skin-to-skin contact has dramatic effects, researchers have drawn on Kolcaba's comfort theory. Ludington-Hoe (2015) suggests that the womb fosters a sense of security, with warmth, the mother's familiar heart beat and voice, her unique scent, and rocking from the mother's breath. With birth creating a very stressful situation for the infant, a mother's skin-to-skin contact brings back a sense of comfort due to the familiar scent, voice, warmth, and rocking, reducing stress (Bystrova et al. 2003). It was shown that the "first 2 to 3 hours are a sensitive period for manifestation and control of stress," meaning that if the newborn received SSC within that time, stress diminished by the third hour of birth, but if the newborn did not receive SSC by its second or third hour after birth, the newborn continued to experience high stress levels. If a newborn receives SSC at birth, they are able to better handle stress 1 year postpartum and that an hour a day of SSC after 32 weeks, reduced stress reactivity at 3 months and at 10 years. When observing cortisol levels, it was shown that after 20 min of SSC, newborn's cortisol decreased by 70% (Gitau et al. 2002).

In terms of skin-to-skin contact reducing pain, Johnston et al. (2009) concluded that SSC alone is better than adding rocking, singing, and suckling to swaddling and facilitative tucking. SSC is a great pain reducer since oxytocin, released during SSC, increases beta-endorphin levels and c-afferent nerve activation, which produces analgesic effects, explaining how the newborns experience less pain by being in skin-to-skin contact with their mothers and caretakers (Liljencrantz and Olausson 2014).

## Conclusions

Contact comfort has been seen to have a great role in developing infant-mother attachment and bonding, while also creating a safety net for infants to allow them to cope with stress and new stimuli. The studies of contact comfort led to the development of attachment theory and skin-to-skin contact with human newborns. Attachment theory granted us the knowledge about the

importance of a caregivers' response to an infants' signal, which will create life-lasting attachment styles to other people. The effects of skin-to-skin contact have many health benefits to infants and newborns, mostly in reducing stress and pain and developing an infant's affection to its mother. SSC is very important for a newborn right after birth, and the benefits can be observed hours to years after SSC. When stress is reduced by having skin-to-skin contact with its mother, a known stimulus, it allows the infant to be more confident in its new environment, promoting exploration, emotional stability, and a healthier environment for the infant to develop. SSC also reduces pain, allowing common procedures to be done with less pain and stress to the newborn.

## Contagion

Thomas R. Zentall

University of Kentucky, Lexington, KY, USA

Behavioral contagion (also referred to as instinctive imitation; Morgan 1900) is a type of social influence that refers to the propensity for certain behavior exhibited by one organism to be copied by others (see sections on imitation, affordance learning, and observational conditioning). Behavioral contagion generally applies to the copying of species typical behavior. That is, it is behavior that does not have to be learned and also will occur in the absence of a social stimulus, although not with the same probability. Examples of naturally occurring contagious behavior are yawning, laughing, crying, and eating. Contagious behavior is sometimes referred to as socially facilitated behavior (see section on social facilitation), but social facilitation more specifically refers to the effect on the behavior of an animal produced by the mere presence of another animal (Zajonc 1965).

The most frequent example of contagious behavior is contagious yawning. Humans yawn when we see another human yawn. Even the sound of yawning, thinking about yawning, or reading about yawning can make a human yawn (Provine, 1986). There are many hypotheses about the function of contagious yawning but it

has generally been viewed as a shared experience that promotes social bonding. Certain kinds of contagious behavior are associated with emotional responses, like laughing and crying, which clearly have an emotional component (see section on emotional contagion) and which are thought to be the basis for the development of human empathy but contagious yawning does not appear to be connected to any particular emotion. Furthermore, contagious yawning also has been found in several nonhuman species such as chimpanzees (Anderson et al. 2004), bonobos (Demuru and Palagi 2012), baboons, (Palagi et al. 2009), wolves (Romero et al. 2014), and, to a certain extent, dogs (Romero et al. 2013) and budgerigars (Gallup et al. 2015).

Neuroscientists have proposed that mirror neurons are involved in contagious yawning (Haker et al. 2013). Mirror neurons are neurons that have been found in the inferior frontal gyrus that fire when an animal performs a particular response as well as when that response is observed to be performed by others.

One of the more interesting examples of behavioral contagion in animals has been found with regard to eating behavior (Rajecki et al. 1976). In this research, food-deprived chickens were given free access to food until eating reached a low baseline level (they were presumably sated). When a food-deprived conspecific was introduced, the sated chickens showed a significant increase in eating as compared to control chickens that ate alone. The authors found similar effects when they conducted the experiments with water-deprived chickens given free access to water and then introduced to another water-deprived chicken.

The finding of contagious eating behavior has important implications for the assessment imitation in animals. Although one would not think of eating behavior as being a low probability behavior in the presence of food (see section on imitation), it may be inferred that the effect of the conspecific on the sated chicken represents an increase in motivation, and an increase in motivation is what is presumed to be responsible for social facilitation (Zajonc 1965; see section on social facilitation).

## Introduction

Yawning is a universal everyday behavior shared by all vertebrate species. It is a stereotyped and often repetitive involuntary motor act characterized by gaping of the mouth and accompanied by a long inspiration of breath, a brief acme, and then a short expiration of breath. Yawning is not merely a simple opening of the mouth but a complex, coordinated movement involving a flexion followed by an extension of the neck and a wide dilatation of the pharyngo-larynx with strong stretching of the diaphragm and antigravity muscles (Provine 1986). Contagious yawning is the urge to yawn when thinking about, listening to, reading about, hearing, or viewing yawning. Ethologists use a better word, i.e., replication, or behavioral mimicry, whereas neurologists refer to echokinesis, a term coined by Jean-Martin Charcot (1825–1893). The widespread familiarity of contagious yawning is due in part to the fact that almost everyone has experienced the phenomenon and it occurs seemingly without volition. This behavior is well documented in humans; however, its function and prevalence in the animal kingdom and the brain mechanisms underlying it are only beginning to be understood.

## Contagious Yawning

Olivier Walusinski  
Family Physician, Private Practice,  
Brou, France

## Synonyms

Chasm; Gap

## Definition

The yawn is a stereotyped and often repetitive motor act characterized by gaping of the mouth accompanied by a long inspiration of breath, a

## Behavioral Framework

Yawning is morphologically similar in reptiles, birds, mammals, and fish, and no environmental input changes the sequence of movements (Walusinski and Deputte 2004). This behavior may be an ancestral vestige maintained throughout evolution with little variation, bearing witness to the early phylogenetic origins of yawning. Like any phylogenetically old behavior, yawning can be observed early in ontogeny, that is, at 12 weeks of fetal life in humans (Walusinski

2012). Behavioral and neurophysiological studies provide converging evidence that yawning occurs preferentially during rest, periods of drowsiness, and awakening. Hunger and satiety also trigger yawning. The frequency of yawning has a distinctive circadian distribution and occurs most frequently before and after sleep, that is, during periods of lower levels of vigilance and alertness (Fica and Salzarulo 2002; Walusinski and Deputte 2004).

When animals transition between behaviors, they are not merely responding in a passive way to the conditions of the environment, such as day-night succession. Rather, they are following internally generated signals produced by homeostatic processes originating in the hypothalamus (suprachiasmatic nucleus and paraventricular nucleus of the hypothalamus, where yawning is triggered). The resultant internal rhythm allows for the anticipation of transitions and triggers behavioral and physiological changes in accordance with those transitions. This results in two advantages: predictability and the possibility to detect the unexpected. Similar to sleep and hunger, yawning functions in this way and appears to be associated with transitions between periods of high and low activity or arousal. This universal form of yawning is internally elicited (Gupta and Mittal 2013; Krestel et al. 2018).

But other, externally elicited forms of yawning exist. Among mammals, morphologically identical yawns occur in situations relative to stress, social interactions, and sexuality (Kubota et al. 2014). Contagious yawning is a form of social interaction without language, triggered involuntarily. Nonconscious mimicry (“chameleon effect”) refers to an individual’s tendency to imitate a social partner’s behaviors without either party’s awareness or intent.

## Yawning in the Animal Kingdom

Yawning conveys information to other conspecifics about dominance, state of arousal or tiredness, anxiety, or fear. The combinations of different types of signals (visual, acoustic, and olfactory) establish the interaction in either

conspecifics or human counterparts. Indeed, a cross-species chameleon effect or contagiousness has now been documented for yawning between dogs and humans (Buttner and Strasser 2014; Harr et al. 2009). In nonhuman primates, teeth-bearing during yawning has led to the suggestion that this behavior reinforces dominant identity rather than signaling a threat (Deputte 1994). Accordingly, yawning has been compared with intimidating displays that dominant males usually show to subordinate males to display their dominant status. Chimpanzees, like humans, differ from Old World monkeys in that yawning by adult males is not a form of ritualized display expressed in situations of male-male confrontation.

Other ethological studies propose that yawning might induce relaxation of social tension and thus be a displacement activity, considered to indicate changes in behavioral state for the yawner and simultaneously to operate as a physiological capacity signal. In Sprague-Dawley rats, yawning associated with penile erections suggests that yawning behavior arises from the ritualization of pre-existing cues involved in perception of stimulating chemo-signals in a mating context (Moyaho et al. 2015).

## Contagious Yawning

Contagious yawning has been observed in non-human primates (chimpanzees, bonobos, stump-tailed macaques, gelada baboons, and common marmosets) (Demuru and Palagi 2012; Palagi et al. 2009), in dogs (Harr et al. 2009), in wolves (Romero et al. 2014), in sheep (Yonezawa et al. 2017), in budgerigars, the only non-mammalian specie (Gallup et al. 2015), in rats (Moyaho et al. 2015), and in elephants (Rossman et al. 2017), but not in lemurs (Reddy et al. 2016) and tortoises (Huber and Wilkinson 2011). No data are available for other species. Animal studies have reported low levels of contagious yawning in dogs, significantly lower than 33%, the rate observed in chimpanzees (Harr et al. 2009). Contagious yawning seems to be more easily triggered when models are conspecifics or have a strong social bond with the observer. The

individuals that are more “reactive” when watching yawning of conspecifics are not more reactive when exposed to other behaviors (Anderson and Matsuzawa 2006).

Observational surveys and experimental analysis of contagious yawning in humans has revealed occurrence in 65%–75% of the entire population. There is still no consensus as to whether women exhibit more contagious yawning than men (Gallup and Massen 2016). At any rate, individuals who conform spontaneously to normative social influence, and who are most receptive to advertising messages, also appear most susceptible to contagious yawning. People who scored higher on measures of empathy and mental state attribution skills were more likely to show contagious yawning (Palagi et al. 2014). These observational data, among others, are produced for linking contagious yawning and empathy.

How is contagious yawning triggered? Sight is a powerful stimulant. In spectators viewing a video showing 30 successive yawns, 55% will yawn within 5 min. The latency period varies from a few seconds to 5 min. There is no need for the face of the yawner to be in a precise visual plane relative to the subject receiving the contagion. Face to face, at 90°, 180°, and 270° relative to one another, replication occurs. The existence of a susceptibility to contagion among blind subjects confirms that sight is not the only trigger. Viewing only part of the face, such as a widely opened mouth, does not trigger replication. Therefore, a multimodal perception of the whole facial configuration and of audible respiratory moments is necessary for replication to happen, along with coordinated dynamics (Provine 1989). By animals as by humans, individual yawning in response to perceiving someone else yawn varies as a function of a host of variables that have yet to be clarified.

## The Neural Basis for Contagious Yawning

Contagious yawning is a primitive expression of cognitive processes involved in self-awareness

and theory-of-mind, that is, the capacity to build knowledge of mental states and to attribute them to others. In humans, contagious yawning first appears around 5 years of age, probably linked to the acquisition of a theory-of-mind. Humans who performed better at self-recognition and theory-of-mind exhibited more contagious yawning (Senju 2010). Yawning operates as a low-level form of nonconscious mimicry, which is necessary for involuntarily decoding the mental states of others, notably their emotions. The link between empathy and contagious yawning has empirical support but remains controversial (Massen and Gallup 2017). In line with this possible association, the empathic modeling hypothesis predicts that species that do not recognize themselves in mirrors and do not show evidence of mental state attribution ought to fail to show evidence of contagious yawning (de Waal and Preston 2017; Provine 2012).

Both developmental and neurophysiological research suggests that resonance between observed and executed actions is supported by the mirror neurons system (MNS). Brain areas that constitute the MNS, namely, the premotor area in the frontal lobe, the inferior parietal lobule, and the superior temporal sulcus, participate in the imitation of motor acts and expressions. These human mirror regions are homologous with area F5 of the ventral premotor cortex in macaques (Rizzolatti 2005). These regions are also interconnected with the insula and show activation in functional MRI studies of imitation, emotional states, and thus, empathy (Anderson and Matsuzawa 2006). The ventromedial prefrontal cortex also integrates affective signals to guide emotionally adapted behaviors. Thus, motor acts and affective states can transfer from a target to an observer in a bottom-up, goal-relevant manner through shared representations for perception and action. In this way, observing an affective posture or expression drives feed-back from peripheral motor representations to activate associated emotional states. Contagious yawning recruits brain areas that have been implicated in social cognition (empathy), self-processing, theory-of-mind, and

emotional contagion mechanisms (motor mimicry-MNS). Contagious yawning is the most basic expression of motor mimicry and emotional contagion, a rudimentary form of involuntary empathy (Brown et al. 2017; de Waal and Preston 2017). Whatever underlies contagious yawning, it does not appear to be based either on conscious imitation or higher-level, “conscious” empathy. Regardless, contagious yawning presents a powerful tool to explore the root of empathy in animal evolution (Provine 2014).

## An Error to Avoid

Equating physiological and communicative functions of yawning with non-social and social contexts, respectively, is inaccurate as both forms may occur in a social context. Indeed, ethological studies of nonhuman primates or South-African ostriches, for example, show that, at certain points, an entire group yawns. In this case, there is no contagious yawning but a synchronous behavior related to circadian rest-activity rhythms.

## Conclusion

Contagious yawning is an example where, through evolution, a behavior can be recycled for different purposes according to the increasing complexity of the central nervous system, correlated with the richness of social interactions. Yawning is managed by the phylogenetically oldest part of the brain, namely, the diencephalon and brainstem. Contagious yawning occurs by neocortex activation, which is necessary for the complex interactions of social life between individuals. It remains to be seen whether contagious yawning has any effect on the activity levels of other group members. Further research, especially in wild populations, should examine the regulating effect of yawning on synchronized group behavior in order to test its communicative function. Contagious yawning offers a neglected but fruitful avenue of investigation in the

growing fields of developmental, affective, and social neuroscience.

Definition

In the area of learning theory, the term *contingency* refers to the extent to which the presence of an event (the *predictor* event) is associated with changes in the probability of occurrence of another event (the *outcome* event).

Main Text

Like correlation, the concept of contingency refers to the degree of covariation between two events. Although contingency can be measured in different ways, an extensively used index is  $\Delta P$  (Allan 1980), which measures the one-way dependency between two binary events. Specifically, for a predictor and an outcome that can be either present or absent this index is equal to the difference between the probability of the outcome event happening when the predictor event is present,  $P(\text{Outcome}|\text{Predictor})$ , and the probability of the outcome event happening when the predictor event is absent,  $P(\text{Outcome}|\sim \text{Predictor})$ :

$$\Delta P = P(\text{Outcome}|\text{Predictor}) - P(\text{Outcome}|\sim \text{Predictor}) \tag{1}$$

We can estimate these two conditional probabilities from our repeated experience with the presence or absence of each of the events. Since the two events are binary, there are four possible combinations: (a) both the predictor and the outcome events occur together, (b) the predictor occurs and the outcome does not, (c) the predictor does not occur and the outcome occurs, and (d)

neither the predictor nor the outcome occur. The frequency with which each of these four possibilities is experienced is typically summarized by constructing a contingency table (see Table 1). Once frequencies  $a$ – $d$  are gathered, the conditional probabilities from Eq. 1 are easily calculated. The  $P(\text{Outcome}|\text{Predictor})$  is calculated by dividing the amount of occasions in which both the predictor and event occurred ( $a$ ) by the total amount of times in which the predictor occurred ( $a + b$ ). Analogously, the  $P(\text{Outcome}|\sim \text{Predictor})$  is calculated by dividing the amount of occasions in which only the outcome occurred ( $c$ ) by the total amount of times in which the predictor did not occur ( $c + d$ ). Therefore, Eq. 1 can be rewritten as:

$$\Delta P = \frac{a}{a + b} - \frac{c}{c + d} \tag{2}$$

The  $\Delta P$  index can take any value between  $-1$  and  $+1$ . Positive values imply that the probability of the outcome event is higher when the predictor is present than when it is absent and, therefore, they are indicative of a positive statistical relationship. Negative values imply that the probability of the outcome is higher when the predictor is absent and they are indicative of a negative relationship. When the index takes a value of zero, the probability of the outcome is unaffected by the presence or absence of the predictor, that is, there is no statistical dependency between the two.

Robert A. Rescorla (1967, 1968, 1969) is known for stressing the central role of contingency in animal classical conditioning. He demonstrated that simple pairings of a neutral stimulus with an unconditioned stimulus did not suffice to guarantee that an association between the two would develop (note that in this context, the

**Contingency, Table 1** A contingency table depicting the four possible combinations of presence and absence of the predictor and the outcome

|            | Outcome | ~Outcome |
|------------|---------|----------|
| Predictor  | $a$     | $b$      |
| ~Predictor | $c$     | $d$      |

neutral stimulus acts as the *predictor* event and the unconditioned stimulus as the *outcome* event). According to the contingency approach to conditioning, for a neutral stimulus to develop an association with an unconditioned stimulus, the former must be able to predict changes in the probability that the latter will occur. That is, the contingency between the two must differ from zero. The greater the contingency, the stronger the expected associative strength. Moreover, the nature of the association will depend on the sign of the contingency: excitatory associations will form between stimuli for which the contingency is positive while inhibitory associations are anticipated if the contingency between the two is negative. In a series of classical fear conditioning experiments, Rescorla confirmed these predictions, showing that rats were sensitive to the programmed contingency both respect to excitatory (Rescorla 1968) and to inhibitory (Rescorla 1969) conditioning (see also Murphy and Baker 2004 for a more recent example of contingency sensitivity in an appetitive conditioning preparation). This general framework can also explain the basic features of several associative learning effects like extinction, latent inhibition, or delayed reinforcement, as they all refer to situations where conditioned responding becomes weaker as a result of degrading the contingency between the predictor event and the outcome event. In any case, the topic is not free of controversy, and some authors have questioned the relevance of contingency in classical conditioning (Papini and Bitterman 1990; but see Baker et al. 2001).

Several studies have shown that human causal learning is also influenced by the contingency between the event that is presented as the potential cause (the predictor) and the effect (the outcome). In causal learning studies, participants are typically presented with a computerized task that asks them to find out to what extent a causal relationship exists (e.g., to what extent a pill is effective in curing a certain disease). After being exposed to several trials in which the presence and absence of the potential cause and of the effect are combined, participants are commonly asked to rate the intensity of the causal relationship existing between the two by making use of a numerical scale. In these

experiments, causal ratings tend to be sensitive to the programmed contingency levels (e.g., Wasserman et al. 1993), although some consistent deviations from  $\Delta P$  are also observed. For instance, it has been observed that, for a given level of contingency, causal judgments tend to covary with both  $P(\text{Outcome})$  and  $P(\text{Predictor})$  (see Perales and Shanks 2007, for a review). Even in noncontingent situations, a conjunction of a high  $P(\text{Outcome})$  and a high  $P(\text{Predictor})$  tends to generate a strong impression of the predictor and the outcome being connected, giving rise to what researchers have called *illusions of causality* or *causal illusions* (see Matute et al. 2015, for a review).

## Contrafreeloading

I. R. Inglis  
Central Science Laboratory, York, UK

## Introduction

Contrafreeloading (CFL) is the behavior shown when an animal prefers to work for food (“earned food”) rather than take identical food that is freely available from another, nearby source (“free food”); for reviews see Osborne (1977), Inglis et al. (1997). This term was coined by Jensen (1963) to describe his finding that rats choose to press repeatedly a foot pedal in order to obtain food rather than freely eat the same food from a bowl. This behavior is important because it appears to contradict several major theoretical frameworks (e.g., optimal foraging theory) that predict animals strive to maximize the ratio of reward, or benefit, to effort, or cost.

Since Jensen’s experiment, CFL has been demonstrated in many species of wild and domesticated mammals (e.g., rat, mouse, gerbil, pig, bear, wolf, macaque, chimpanzee, human) and birds (e.g., pigeon, chicken, jungle fowl, starling, crow) with only a very few species, e.g., the domestic cat, not showing this behavior. CFL has also been found when water rather than food is used and when the rewards are not nutritional (e.g., access to brief video clips, coins).

CFL has been most commonly studied by presenting the animal with a choice between free access to a bowl of food, and an operant task that provides response-dependent access to the same food. The schedule of reinforcement has varied between continuous reinforcement, fixed-ratio schedules, and variable-ratio schedules. Rather than have continuously available free food, some experiments have presented a choice between response-independent and response-dependent food. Nonoperant paradigms have also been employed, particularly when wild species were involved. For example, animals in mazes will take a long indirect way to food rather than a shorter direct route. They will also search or solve puzzles for food rather than take the same food from a bowl.

The criterion for a preference in CFL studies has been defined in various ways. In his review, Osborne (1977) concluded that a preference for a food source exists when the proportion of the total food obtained from that source exceeds 50% of the total food obtained during the session. However, there is no reason to suppose that 50% represents a magic point of discontinuity for the animal between “preference” and “non-preference.” Indeed as already mentioned, paradigms such as optimal-foraging theory predict there should be a total preference for the free food.

## Factors Affecting the Strength of CFL

### Training

The level of pretrial training in the response required to obtain the earned food significantly affects the subsequent level of CFL. During CFL the percentage of the pellets obtained that were

earned by, for example, bar pressing has been found both to increase and to decrease, with the number of rewarded responses made during training before the experimental trial. A possible explanation for these contradictory results is discussed later. Although prior training clearly affects the level of CFL, convincing evidence that CFL cannot solely be a function of training comes from the many experiments showing that it can be acquired and maintained when there is both no training in the response required and continuous access to free food.

### Deprivation Level

Animals do not have to be hungry in order to show CFL: many studies have found high levels of such behavior under conditions of zero deprivation. In addition animals often do not eat all of the pellets they obtain by working. Rather it has been shown that increasing hunger decreases CFL. Since hunger will decline throughout the trial, as a result of the uptake of food, the within-trial changes in the proportion of food obtained by CFL also shed light on the effect of hunger level. It has generally been found that CFL is lowest at the beginning of the trial and then increases over the trial as hunger level falls.

### Effort Required

Increasing the effort required to obtain the earned food (e.g., by raising the number of lever presses required for each pellet of food delivered) reduces CFL. However, it is not just the effort required to obtain the earned food that is important. Mitchell et al. (1982) compared the level of CFL in rats when the free food was placed in either a tall dish, which necessitated the animals climbing up the sides, or a short dish, which required no climbing. The rats with the tall free-food containers showed the greater CFL. The relative effort required to eat at the two food sources is the important factor.

### Rearing Conditions

Animals reared under sensory deprivation, or maintained under it for a long period of time during adulthood, explore more when faced with

a novel object than do animals kept under sensory enriched conditions. Similarly rats reared under conditions of sensory impoverishment show more CFL than those reared under sensory enriched conditions. Clear evidence of a link between exploratory behavior and CFL comes from the study of Nau et al. (1981). Three groups of rats were reared under different sensory conditions and then tested in a novel maze as well as under the CFL paradigm. As with the earlier studies, the rats reared under sensory enriched conditions showed the least CFL, but, in addition, it was found that the animals showing the most exploration in the maze were also those that exhibited the highest level of CFL.

### Stimulus Change

CFL is strongly affected by stimulus changes correlated with the presentation of the earned food. If visual and/or acoustic stimuli normally associated with the delivery of the earned food are removed, then CFL falls to near zero, and it recovers when these stimuli are reinstated. Working for earned food in the absence of associated stimulus changes is not sufficient to maintain CFL in an operant situation. However, it has also been found that response-produced stimulus change alone is not sufficient to maintain responding in the presence of free food. Animals work for their food only when the operant responses produce both food and stimulus change.

The degree of response-contingent stimulus change influences the level of CFL. For example, following a condition in which no stimulus was contingent upon obtaining earned food, and where there was negligible CFL, Osborne and Shelby (1975) paired the presentation of the earned food with an acoustic stimulus for one group of rats and with a visual stimulus for another group. The addition of the stimuli greatly increased and maintained CFL. When both groups later received both auditory and visual stimuli, responding was enhanced above the level of CFL maintained by either stimulus alone. It has been found that most CFL occurs when the stimuli associated with the earned food are neither very familiar nor very novel.

### Environmental Uncertainty

CFL is found in nonoperant paradigms that lack a clear response-contingent stimulus as long as uncertainty is associated with the food-gathering task. For example, in the experiment of Havelka (1956), rats entered a long goalbox containing eight alcoves arranged in two groups of four. In the group of alcoves near the entrance to the goalbox, the food was always placed in the same alcove, the “constant dish.” The other group of four alcoves was at the far end of the goalbox, and here which alcove contained the food was randomly chosen on each trial, the “variable dish.” Rats passed the first set of alcoves, ran down the goalbox, and searched the second set for the variable dish. However, when the variable dish was then kept in the same alcove on each trial, the rats shifted their preference to the dish in the set of alcoves nearest the goalbox entrance. When the uncertainty over the location of the variable dish was removed, CFL ceased. Similarly in the study of Forkman (1996), gerbils were given a choice between foraging in a site with easily accessed food, or from a site requiring a lot more work. When the amount of food available at both sites could be immediately and easily accessed, the animals preferred the most profitable food source. However, when uncertainty was associated with the least profitable food source, i.e., the food there was hidden under lids or was camouflaged, then the animals choose to work at this site. Bean et al. (1999) obtained supporting results from similar experiments conducted with starlings. They concluded that CFL is reduced when there are ways to gather information about the food patches other than by working for the food.

### Explanations for CFL

In their review, Inglis et al. (1997) concluded that, in addition to training, there were three major factors that controlled the level of CFL. First, most CFL occurs when the stimuli associated with the earned food are neither very familiar nor very novel. Second, CFL declines with increasing hunger. Third, an increase in effort to

obtain the earned food relative to the free food reduces CFL. They developed a mathematical model to simulate interactions between these factors and found it was able to account for the majority of the results published in the CFL literature. This still, of course, does not answer the question why do animals show CFL, particularly in the absence of any training?

### Training Effects

The effect of training on CFL could be the result of neophobia towards the free-food container since, while the animals had received operant training before the test, they had no prior experience of the free-food container. Mitchell et al. (1973) found that CFL was indeed negatively correlated with the familiarity of the free-food container. However, neophobia towards a novel free-food container should be greatest at the beginning of a trial and then gradually decline, and yet, as already mentioned, most feeding from the free-food container takes place at the start of the trial rather than at the end. Also this hypothesis cannot account for the CFL found in experiments where there was equal exposure to both food sources.

Two explanations have been proposed to explain why response-contingent stimulus change affects CFL. The first argues that after its repeated pairing with food presentation during training, the stimulus change becomes a secondary reinforcer. Clearly this explanation cannot account for the CFL that occurs in the absence of any training. The second explanation is that the response-contingent stimulus change is reinforcing in its own right. There is an established body of literature demonstrating that satiated animals will work solely to experience simple stimulus changes (e.g., see Kish 1966) and thus during CFL the animal is not working for food alone but for food plus sensory reinforcement. The combined reinforcement is thought to be sufficient to maintain responding for earned food in the presence of free food (Osborne and Shelby 1975). This explanation can account for CFL in the absence of training since the stimulus change should be effective from the outset.

As already mentioned, CFL has been found both to increase and to decrease with increasing numbers of training trials. If CFL is the result of sensory reinforcement, then it should decline with increasing number of training trials because greater satiation to the response-contingent stimulus change will occur. On the other hand, if secondary reinforcement is the main causal factor, then increasing the pairings between stimulus change and earned food during training will increase CFL. These two explanations are not mutually exclusive. The number of training trials will determine which effect dominates during the test period. With only a few or no training trials sensory reinforcement effects will dominate since there will be too few pairings of the stimulus change with earned food to establish it as a strong secondary reinforcer. As the number of training trials increases, there will be greater satiation of the sensory reinforcement effect and strengthening of the secondary reinforcer effect.

### **The Response Used to Obtain the Earned-Food is Self-Reinforcing**

It has been suggested that CFL occurs because the performance of the task required to obtain the earned food is reinforcing in its own right. This intrinsic reinforcement is thought to arise when the task is part of innate behavior patterns connected with appetitive and/or consummatory acts. For example, the domestic pig does not show CFL when tested using an operant response in a controlled environment, but it does when a more natural foraging task is required to obtain the earned food. However, this explanation cannot explain why, in many other species, CFL does occur when the action required to obtain the earned food involves behaviors that are not natural and have to be learned. Also CFL is found where the same behavior is required to get both earned food and free food. More importantly, as already discussed, animals stop CFL as soon as the behavioral response no longer produces the earned food, suggesting that just performing the act itself is not reinforcing. Forkman (1993) explicitly investigated this question. One group of gerbils were, for 20 min

per day for 5 days, given access to a cage containing a bowl of sunflower seeds and a bowl containing sand plus 30 sunflower seeds. After 5 days, the procedure was repeated with the cage containing a bowl of sunflower seeds and a bowl of just sand. The treatments were reversed for another group of gerbils. It was found that for both groups practically all digging took place in the bowl with 30 seeds. When this bowl contained just sand digging fell dramatically and there was no compensatory digging elsewhere in the cage. Clearly the digging per se was not self-reinforcing.

### **Competence Theory**

Some authors have explained CFL in terms of White's Competence Theory. White (1959) argued that behavior is primarily directed towards manipulating and controlling the environment and that such behavior is self-reinforcing. This theoretical position has more recently been restated in the concept of animal agency, i.e., that the animal is an active agent continually seeking to deal effectively with its environment (e.g., Wemelsfelder and Birke 1997). In the CFL paradigm, obtaining the earned food usually involves greater environmental manipulation than simply taking the free food from a dish. If this hypothesis is correct then animals should prefer to work for response-dependent food rather than take response-independent food delivered at the same rate. The studies of Singh (1970) and Morgan (1974) found that this was indeed the case. However, while it has been shown that animals give priority to being able to exercise control over minimizing effort, it is not clear how Competence Theory can account for the relationship between CFL and hunger and that between CFL and uncertainty associated with the earned food. It does also not explain why CFL can occur when the same behavior is required to obtain both free and earned food.

### **Information-Primacy Hypothesis**

Inglis et al. (1997) suggested that CFL is a form of self-reinforcing exploration and as such it could be explained in terms of the information-primacy

hypothesis (Inglis 1983, 2000). This argues that in complex and stochastic environments the ability to cope with the unexpected is essential for survival and that in order to deal with uncertainty the animal constructs models of its environment that enable predictions to be made. Such models require constant update and thus the continual gathering of information about uncertain events is vital for animals living in such environments. This ongoing behavior forms a substratum upon which other, more obviously goal directed, behaviors occur. Only when need states, like hunger, become intense enough to interrupt the information-gathering behavior do animals focus exclusively upon fulfilling those needs. Thus, in CFL animals work for the earned food partly for the food itself and partly to improve and update their estimate of the profitability of an uncertain food source that may unpredictably become the optimal place to feed. This explanation can account for the facts (a) that, in the absence of training, CFL only happens if some uncertainty is associated with obtaining the earned food, (b) that CFL declines with increasing hunger, and (c) that there is a correlation between CFL and intrinsic exploration.

Bean et al. (1999, with starlings) and Lindqvist et al. (2002, with jungle fowl and domestic fowl) tested whether animals used any information they may have gained while CFL to inform future foraging decisions. When the birds were presented with food patches containing different amounts of food mixed with filler, they showed CFL by feeding at the less profitable patches. After being food deprived, the birds were again presented with the patches but with the most profitable patch removed. They reliably choose the second best patch on the first approach.

Inglis et al. (1997) suggested that if CFL occurs in order to gain information about uncertain food patches, then it should be weak in a species whose environment does not necessitate searching for unpredictable food items. Domestic animals usually live under such conditions and Lindqvist et al. (2002) have reported that domesticated strains of fowl do indeed show less CFL than does the wild jungle fowl.

## Conclusion

Working for food when the same food was freely available nearby was initially regarded as a strange behavior shown by laboratory rats and pigeons that arose as a result of procedures adopted during the training of the operant responses required to obtain the earned food. However, subsequently it was found that a large number of wild species showed CFL when tested under a wide range of naturalistic experimental situations that did not require any training. CFL is now regarded as a normal behavior that sheds light on the ways animals cope with surviving in variable and unpredictable habitats.

Situations that allow animals to show CFL are increasingly used to improve the welfare of captive animals. Many studies have demonstrated that inadequacies in the captive environment (e.g., impoverished sensory surroundings) result in poor animal welfare, as shown by abnormal behaviors and negative psychological states such as stress. Environmental enrichment can reduce, and prevent the development of, poor welfare and giving captive animals opportunities to show CFL, for example, to search for their food rather than simply have it presented to them in a trough, has become one of the main forms of such enrichment.

## Contrapreparedness

Stephen B. Klein

Mississippi State University, Starkville, MS, USA

## Introduction

What does the term contrapreparedness mean? Martin Seligman introduced the term in his 1970 *Psychological Review* article. According to Seligman, animals have an evolutionary preparedness to associate some stimuli with a biological significant event or an unconditioned stimulus, but that other associations cannot be learned. In Seligman view, the concept of **contrapreparedness** refers to the fact that some stimuli, despite repeated pairings, cannot become associated with a specific unconditioned stimulus. The likelihood that a particular neutral stimulus will become able to elicit a conditioned response after pairing with an unconditioned stimulus reflects the salience of the neutral stimulus. Seligman proposed that preparedness makes a stimulus more salient, while contrapreparedness make a stimulus less or non-salient. In other words, salient stimuli rapidly become associated with a particular unconditioned stimulus, while nonsalient stimuli do not, despite repeated pairings, become associated with that unconditioned stimulus.

William Timberlake in 2001 suggested that the variations in what an animal can learn reflect either to predispositions or constraints. A predisposition refers to instances in which an animal learns more rapidly or in a different form than expected. Timberlake suggests that predispositions occur when environmental circumstance easily modifies the instinctive behavior system that the animal brings into the situation. Variations in learning also can reflect the impact of a constraint on learning; a constraint occurs when an animal learns less rapidly or less completely than expected. According to Timberlake, constraints on learning occur when environmental circumstance is not suited to the animal's instinctive behavior system. Several examples of contrapreparedness are presented in the next several paragraphs.

## Stimulus Salience

John Garcia examined the relative salience of stimuli paired with illness and electric shock. In the classic study by Garcia and Koelling in 1966, rats received either a saccharin taste cue or a light and tone compound stimulus. Following exposure to one of these cues, the animals received either an electric shock or irradiation-induced illness. Garcia and Koelling found that rats exhibited an aversion to saccharin when it was paired with illness but not when it was paired with shock. In addition, they developed a fear of the light and tone stimulus when it was paired with shock but not when paired with illness. Based on the results of this study, rats seem contraprepared to associate a taste cue with an electric shock or a light-tone stimulus with illness.

In his 1970 article, Seligman suggested that rats have an evolutionary preparedness to associate tastes with illness. This view is consistent with the observation that adult rats acquire an intense aversion to a flavor after a single taste-illness pairing. My colleagues and I also found that young rats also acquire a strong aversion after one pairing (Klein et al. 1975). Apparently, taste cues are very salient in terms of their associability with illness.

Seligman also proposed that rats are contraprepared to become afraid of a light or tone paired with illness. My colleagues and I did observe that animals avoided a distinctive black compartment previously paired with an illness-inducing apomorphine or lithium chloride injection (Klein et al. 1985). It should be noted that environmental events (distinctive places) are not very salient when paired with illness as many trials and careful training procedures are necessary to establish an environmental aversion unlike the single-trial learning of a flavor aversion (Riccio and Haroutunian 1977). It would seem that rats are contraprepared to associate a distinctive environment with illness.

It should be noted that while rats form flavor aversions much more readily than environmental aversions, other species do not show this pattern of stimulus salience. Unlike rats, birds acquire aversions to visual events significantly more

rapidly than they do taste aversions (Wilcoxon et al. 1971). Braveman (1974, 1975) suggested that the feeding time of a particular species determines the relative salience of stimuli becoming associated with illness. Rats, which are nocturnal animals, locate their food at night and therefore rely less on visual information than on gustatory information to identify poisoned food. In contrast, birds search for their food during the day, and visual information plays an important role in controlling their food intake.

## Species-Specific Defense Reactions

How quickly can an animal avoid adversity? Robert Bolles (1970, 1978) proposed that animals have little opportunity to learn a new behavior to avoid aversive events. Animals either possess instinctive means of avoiding danger, which he calls species-specific defense reactions or they perish. A deer does not have time to learn to avoid its predator. Unless the deer possesses an instinct for avoiding predators, it will probably wind up as a predator's meal. Bolles found that animals easily learn to run, a species-specific defense response, to avoid being shocked. Similarly, pigeons easily learn to avoid shock by flying from perch to perch. In contrast, animals have great difficulty learning to avoid an aversive event using a non-species-specific defense response to avoid an aversive event. For example, D'Amato and Schiff (1964) reported that over half their rats, even after having participated in more than 7000 trials over a 4-month period, failed to learn to bar press to avoidance shock.

Contrapreparedness also has been found to influence the acquisition of defensive behaviors in humans. Barbara Fredrickson's (2003) broaden and build theory suggests that positive emotions expands a human's attention and allows an individual to acquire new behaviors to obtain reinforcement. By contrast, negative emotions restrict a human's attention and limit one behavioral repertoire to very limited survival-oriented actions. Just as was true of Robert Bolles' species-specific defense reactions, humans are contraprepared to acquire new ways of avoiding aversive events.

## Animal Misbehavior

The research of Keller and Marion Breland suggests that contrapreparedness also influences whether or not an animal is able to learn an operant behavior to obtain reinforcement. Breland and Breland (1961, 1966) were able to use food reinforcement to operant condition a number of unusual behaviors such as a racoon putting a coin in a "piggy bank" or a rabbit playing a piano. However, the Brelands observed that some operant responses, although initially performed effectively, deteriorated with continued training despite repeated food reinforcements.

The Breland's suggested that the elicitation of instinctive food-foraging and food-handling behaviors caused by the presentation of food reinforcements lead to the decline of an operant response. These instinctive feeding-and-foraging behaviors were strengthened by food reinforcement and eventually prevented the operant behavior. They called the deterioration of an operant behavior with continued reinforcement instinctive drift, and the instinctive feeding-and-foraging behaviors that prevented the operant response an example of animal misbehavior.

Animal misbehavior is an example of contrapreparedness preventing an appetitive operant appetitive response. One example of animal misbehavior is described next. Breland and Breland (1961) attempted to train pigs to pick up a large wooden coin and deposit it in a "piggy bank" several feet away. Each pig was required to deposit four or five coins to receive one reinforcement. According to Breland and Breland, "pigs condition very rapidly, they have no trouble taking ratios, they have ravenous appetites (naturally), and in many ways are the most trainable animals we have worked with" (p. 683). Each pig exhibited an interesting pattern of behavior during conditioning. At first, the pigs picked up a coin, carried it rapidly to the bank, deposited it, and readily returned for another coin. However, over a period of weeks, the pigs' operant behavior became slower and slower. Each pig still rapidly approached the coin, but rather than carry it immediately over to the bank, the pigs "would repeatedly drop it, root it, drop it again, root it along the

way, pick it up, toss it up in the air, drop it, root it some more, and so on" (p. 683).

Why did the pigs' operant behavior deteriorate during conditioning? The Brelands suggested that the presentation of food during conditioning not only reinforced the operant response, it also elicited instinctive food-related behaviors. Food reinforcement strengthened these instinctive food-gathering and food-handling behaviors, which resulted in the deterioration of the pigs' operant depositing response. The more dominant the instinctive food-related behaviors became, the longer it took for the operant response to occur. The slow deterioration of the operant response during conditioning is an example of contrapreparedness preventing the conditioning of the operant behavior (depositing the coin in the bank).

## Conclusion

The concept of contrapreparedness refers to the fact that some stimuli, despite repeated pairings, cannot become associated with a specific unconditioned stimulus. Contrapreparedness make a stimulus less or nonsalient and nonsalient stimuli do not, despite repeated pairings, become associated with that unconditioned stimulus. Contrapreparedness also prevents the learning of defensive behaviors to avoid adversity or when instinctive feeding and foraging behaviors interfere with the acquisition of appetitive operant behavior.

## Contrast Effects

Anna H. Casey  
Duke University, Durham, NC, USA

## Synonyms

[Behavioral contrast](#); [Crespi effects](#); [Frustration effects](#)

## Definition

In associative learning, contrast effects are changes in the strength of a subject's response in one context following a change in the reinforcement of that response in another context. An increase in response strength in one context

following a decrease in reinforcement rate or power of that same response in a second context is known as positive contrast. Negative contrast is a decrease in response strength in one context following an increase in reinforcement rate or power of that response in another context.

## Introduction

The first experiment to systematically demonstrate contrast effects was conducted by Leo Crespi in 1942. Crespi measured the running speed of three groups of rats down an alley to rewards of 1, 4, or 16 pellets. He then changed the reward for the first two groups to match that of the third, namely, 16 pellets. Crespi found that rats in the original four-pellet group ran faster than rats that started with 16 pellets, and that rats in the one-pellet group ran faster than rats in the four-pellet group. This increase in speed was positive contrast resulting from a shift in the amount of reward given for the running behavior. A second experiment by Crespi demonstrated negative contrast. Rats began by running to rewards of 16, 64, or 256. The latter two groups were then switched to a 16-pellet reward. As Crespi predicted from his first experiment, he found that rats in the latter two groups ran more slowly once the reward amount shifted, with the 64-pellet group running slower than the 16-pellet group, and the 256-pellet group running slower than the 64-pellet group. Crespi concluded that these behavioral response shifts could be attributed to an “expectation” of reward coupled with an emotional response. Subjects who found the magnitude of the reward to be greater than expected experienced an elation effect, while subjects who found a lower magnitude of reward than expected experienced frustration.

## Explaining Contrast

While the exact cause of contrast effects has been debated, several studies seem to support the notion that contrast effects are mediated by emotion or psychological state. Smaller contrast

effects are seen, for example, under the effects of barbiturates (Ridgers and Gray 1973). As well, animals that have experience in situations that may produce frustration, such as reward delays (Ferrel and Shanab 1975) or shock punishment training (Rosellini and Terris 1975), exhibit lower levels of contrast. However, developing formal theories to explain contrast is difficult, since learning theory avoids explanations that involve subjective inner motivations, such as emotion.

### Demonstrating Contrast

Two ways of demonstrating behavioral contrast have been explored. In one demonstration, known as simultaneous contrast, two stimuli are presented concurrently, and a change in the reward of one stimulus results in a change in response to the second stimulus. For example, Reynolds (1961) trained pigeons to key peck at a red or green light, which both produced the same reward. He then shifted the green light to an extinction schedule, so that pecks to that light no longer produced a reward. He found a positive shift in response to the red light. In other words, when pecks to the green light no longer produced a reward, pecks to the red light increased, despite no change in reward for the red light.

The second method of demonstrating contrast is to change the reinforcement for a certain task after a period of learning. In this kind of experiment, the shift in context is just a change in time, and this type of effect is known as successive contrast. For example, Crespi's (1942) rats were first receiving four pellets, and then were shifted to 16, causing an increase in running speed. This increase was a positive contrast effect associated with the change in time, since at an earlier period subjects were receiving a lesser reward.

In both of the above examples, subjects are discriminating between two contexts: stimuli color in the first, or time in the second. Discrimination is a necessary component of contrast, and contrast can be used as a measure of a subject's ability to discriminate between stimuli or contexts.

### Ceiling Effects

In experiments that produce contrast effects, negative contrast is often more marked and easier to measure. A subject may only respond so strongly or frequently to a stimulus. Therefore, increases in response, as seen in positive contrast, may hit a ceiling. Bower (1961) first hypothesized this ceiling. In his experiment, rats ran down one of two runways distinguished by the color of their walls. Down one runway, subjects would find a reward of eight pellets, but down the other, they would find one pellet. Two control groups ran as well, with one group only ever receiving one pellet, and the other receiving eight pellets at the end of their runways. Bower found that while subjects that originally ran the eight-pellet runway slowed down when placed in the one-pellet runway, running significantly slower than the one-pellet control group, no effect was found for subjects who switched from the one-pellet to the eight-pellet runway when compared to the eight pellet control group. He proposed that subjects in both the control and experimental groups must have run at their maximum speed for such a large reward. Experimenters must, therefore, consider such response ceilings when attempting to provoke a positive contrast effect.

### Variables Affecting Contrast

Several aspects of an experiment may affect the magnitude of behavioral contrast obtained. Greater disparities between the rewards in the two different contexts can produce greater disparities in response to those contexts. As well, motivation can affect contrast; subjects that are food deprived show higher levels of behavioral contrast than less food-motivated subjects (Cleland et al. 1969; Ehrenfreund 1971; Flaherty and Kelly 1973). In successive contrast experiments, the amount of time in between the presentation of one context and the next will affect contrast effects. For example, if subjects are presented with a smaller reward first, and then shifted to a larger reward, the amount of time in between the smaller reward presentation and the larger reward

presentation will influence behavioral contrast. Longer intervals result in smaller contrast effects (Gonzalez et al. 1973).

## Conclusion

The debate over what causes behavioral contrast continues in the field of associative learning. Several explanations, including frustration and expectation, have been offered. What is clear is that, as in other areas of learning, context is key. Behavioral contrast can only be produced when a subject is able to distinguish between contexts. Contrast effects, therefore, continue to be important and oft-used measures of discrimination and reinforcement in animal learning experiments.

## Convergent Evolution

Alyson Myers

Florida Atlantic University, Boca Raton, FL, USA

## Definition

**Convergent Evolution:** Convergent evolution is the process by which phylogenetically unrelated species have similar adaptations as a result of similar environmental pressures.

## Introduction

*Convergent evolution* involves different lineages independently evolving similar traits. This is the result of different species experiencing similar environmental pressures. If two distinct species live in similar environments, it is reasonable to predict that they will experience similar selection pressures and thus evolve similar traits. These species will possess the same adaptive solution to a shared environmental obstacle to reproductive success, despite their ancestral lineages

having different attributes and genes (Alcock 2013). Unrelated species should behave differently, unless they have experienced similar selection pressures. The opposite of convergent evolution is *divergent evolution*, by which related species evolve dissimilar traits due to variations in their environments, thus resulting in different selection pressures and adaptive solutions.

Convergent evolution can occur at the structural and functional level. Structures that are the result of convergent evolution are called *analogous structures*. On the other hand, a *homologous structure* would have a common origin. Analogous structures refer to unrelated organisms having structures that have the same function but are anatomically different. These similar characteristics were not present in their common ancestor, and the larger the phylogenetic separation of the two species, the more likely the shared trait is due to convergence (Papini 2002). As these adaptations have evolved separately among distantly related species, any similarities can be attributed to shared environmental selection pressures and not characteristics that were present in a common ancestor (Ridley 1993). Convergence can occur in various combinations of structure and function. It can occur at the functional level but not structural and can also occur in structure as well as function.

## Functional Convergent Evolution

Convergence can occur on the level of function, but not structure, as exemplified by flight (Seed et al. 2009). Insects, birds, pterosaurs, and bats all evolved the capability of flight (i.e., the function), while their structures for flight are anatomically different. None of these species are closely related phylogenetically; nevertheless, they evolved the similar function of flight. The structures and mechanisms used to achieve the behavioral outcome of flight are also very different. The wings of an insect are very different than those of a bird or a bat. In birds, flight evolved through the extension of the forelimb bones. However, in bats and pterosaurs, the wing is supported by extended digits. The fifth digit is extended in pterosaurs,

whereas the second, third, fourth, and fifth digits are extended in bats. The convergent evolution of wings for flight are the result of the functional constraints of flight in addition to environmental selection pressures (Van Horik et al. 2012). Each species has a mechanically different method to achieve the same function of flight.

## Convergent Evolution at the Structural and Functional Level

Convergence can also occur at both the structural and functional level, meaning that two independent lineages may evolve the same structure for the same function. This can be seen in distantly related marine mammals. Seals and whales both evolved short-wavelength colorblindness, which is adaptive for sight in the marine visual environment in coastal marine mammals. The colorblindness was achieved similarly with both species losing S-opsin cones in the retina (Peichl et al. 2001). These two distantly related groups of marine mammals converged in having the same structure for the same function of short wavelength colorblindness.

Another interesting example of convergent evolution lies with lamnid sharks, the most popular being the great white and the mako, and tunas. It has been established that hydromechanical and physical selection pressures were important in the evolution of thunniform body shapes in several groups of vertebrates, including whales, ichthyosaurs, and some species of large pelagic, or open ocean, fish. However, in lamnid sharks and tunas, the convergence is furthered as they possess morphological and functional adaptations that are unlike other fishes (Donley et al. 2004). The thunniform body shape that both tunas and lamnid sharks possess exhibits the least undulatory mode of locomotion. The two species' evolutionary pathways converged on the same mechanical design principle (Donley et al. 2004). Both lamnid sharks and tunas have internalized red muscle, which is associated with a force-transmission system (Donley et al. 2004). This morphology transmits forces posteriorly allowing for their thunniform swimming mode. These shared

characteristics most likely evolved due to the selection for continuous and fast movement. Not only are the bodies of large pelagic cruisers shaped by their environments but their morphology and internal physiology is also shaped. The convergence between lamnid sharks and tunas is a good example of convergent evolution occurring at both morphological and functional levels in two distinct species.

## Behavioral Convergent Evolution

Convergent evolution can also be observed in behavior, whereby similar selection pressures in two separate species results in similar behaviors as an adaptive response to the environment. Mobbing behavior in different species of birds is a good example of behavioral convergence. Both ground-nesting gulls and bank swallows along with other colonial swallows, exhibit mobbing behavior (Sordahl 2004). Gulls and swallows are in two different taxonomic families, the Laridae and the Hirundidae. The common ancestor of gulls and swallows lived eons ago, as exemplified by the distinct taxonomic differences. Bank swallows are distinct from gulls genetically and evolutionarily; however, they exhibit similar nesting behaviors. Both bank swallows and gulls nest in colonies where blue jays and predatory snakes feed on nestlings and eggs (Hoogland and Sherman 1976). Due to the similar selection pressures experienced by bank swallows and gulls, they have developed similar mobbing behaviors. The birds swirl and dive at their predators, which distracts the snakes and blue jays from attacking and killing their offspring, thus increasing their reproductive success. Both bank swallows and gulls, although genetically and phylogenetically distinct, have evolved similar behaviors as an adaptive solution to the shared environmental problem of predators destroying their offspring.

Colonial nesting mammals have also developed mobbing behavior in response predators, another example of convergent evolution. California ground squirrels are group living and burrow into the ground. They react to a hunting rattlesnake by surrounding it and shaking their

infrared emitting tails. If the snake does not retreat, they will kick sand in its face, making it difficult for the snake to hunt and often resulting in the rattlesnake retreating (Owings and Coss 1977). Mobbing appears to have evolved as an antipredator adaptation. It appears in a variety of species through convergent evolution as an adaptive solution to predators that attack and destroy offspring.

## Cognitive Convergent Evolution

Convergence not only occurs at structural, functional, and behavioral levels but can also occur at the cognitive level. Distantly related species that experience similar socio-ecological problems will develop similar adaptive traits to handle these problems. At first glance, corvids (crows, jays, and rooks) and parrots seem to have little in common in proportion to body size as apes (Van Horik et al. 2012). Both have large encephalization quotients, which is the brain-to-body ratio, meaning their brains are large relative to their body size. Additionally, the relative size of the forebrain in corvids and parrots is much larger than other birds (Emery and Clayton 2004). Corvids and parrots also demonstrate cognitive abilities similar to large-brained mammals such as primates, cetaceans, and elephants. Whereas the structure of avian and mammalian brains differ, they share advanced cognitive abilities (Emery and Clayton 2004). For example, in the mammalian brain, the neocortex mediates cognitive processes such as, social intelligence, memory, reasoning, and concept formation. However, in the avian brain, there is no neocortex and these processes have been found to be associated with the forebrain. These areas are analogous to the prefrontal cortex in mammals (Van Horik et al. 2012). One of the important components of the evolution of intelligence is thought to be sociality (Van Horik et al. 2012). Complex social interactions have been observed in primates (De Waal 1982), cetaceans (Marino 2002), and corvids (Emery et al. 2007b). As these species are all social living and demonstrate complex social behaviors, a theory of convergence of social cognition is supported.

A term dubbed “chimpanzee politics” has been used to describe the sophisticated social interactions of primates (De Waal 1982). As social-living species, they often forage together in the same areas for the same resources, which can result in direct competition or cooperation. Cetaceans and primates are capable of complex cooperative actions. They create cooperative coalitions among males and also exhibit alloparental care. In primate species, chimpanzees will baby-sit juveniles to protect them from predation (Nicolson 1986). Bottlenose dolphins (Brown and Norris 1956; Herzing and Johnson 1997), spinner dolphins (Norris and Johnson 1994), Atlantic spotted dolphins (Weinpress and Herzing 2015), sperm whales (Whitehead 1996), and other cetaceans also exhibit alloparental behavior.

Primates and cetaceans also exhibit cooperative behavior in their feeding strategies. Chimpanzees exhibit a cooperative hunting strategy when preying on red colobus monkeys (Boesch 1994). The chimpanzees coordinate their behavior in order to successfully hunt and capture their prey. Killer whales have been observed to cooperate and coordinate their behavior while feeding on herring (Similä 1997), and Humpback whales exhibit cooperative bubble net feeding (Jurasz and Jurasz 1979), in addition to other examples in cetaceans. The sociality in these species has led to advanced social cognition, which can be observed in their alloparental behavior and cooperative feeding strategies.

In addition to sharing patterns of social behavior such as cooperation during alloparenting and feeding, cetaceans and primates provide the strongest evidence for social convergence (Marino 2002). Although birds and elephants may also possess culture, the transmission of nongenetic information across generations, the most evidence appears to be in primate and cetacean species. Primates and cetaceans transmit behavioral traditions, such as tool creation and use, across generations. In primates, chimpanzees (Boesch 1994; Whiten et al. 2005) and Japanese macaques (Huffman 1996) have been observed to transmit information about tools. Tool use by means of sponge carrying has also been observed and transmitted across generations in bottlenose dolphins

(Smolker et al. 1997). In a nonmammalian species, tool use has been observed in New Caledonian crows that use and transport tools they have created for their daily foraging expeditions. They also change the tools depending on the functional requirements (Hunt 1996). However, tool use in birds may be functionally limited, as they possess a multifunctional beak that can often act as a tool itself (Van Horik et al. 2012). In addition to tool use in cetaceans, there are cultural traditions with dialects (Whitehead 1998) and prey capture in bottlenose dolphins (Petricig 1993) among other social behaviors.

There is no doubt that sociality in these species presents certain selection pressures that led to convergence of behaviors. Many species of cetaceans and primates live in fission-fusion societies and face challenges with adjusting to dynamic social changes. Some species of birds also, such as rooks, exhibit high levels of sociality similar to chimpanzees and cetaceans (Van Horik et al. 2012). However, some species of birds that exhibit high sociality do not live in fission-fusion societies as they are monogamous maters. This suggests that the social intelligence in these birds may have evolved as a response to the maintenance of social relationships and cooperative behavior between monogamous mates (Emery et al. 2007b). Additionally, the largest relative brain size in birds are found in the long-term monogamous and cooperative breeding species (Emery et al. 2007a).

## Conclusion

Convergent evolution occurs on many levels, structural, functional, and behavioral. These levels are not mutually exclusive, nor do they always occur together. As discussed, convergent evolution occurs when distinct lineages evolve similar traits due to similar environmental pressures. The distinct lineages face similar adaptive problems and thus evolve similar adaptive solutions in order to further their reproductive success. It is worth noting that evolution is not forward thinking – these adaptations develop as the result of selection pressures, whereby the trait that

promotes survival to reproductive age is favored by selection. When species have similar environments, they experience similar adaptive problems, leading to similar adaptive solutions. As reviewed here, convergent evolution can occur at the structural and functional levels, for example, short wavelength colorblindness in seals and coastal whales (Peichl et al. 2001). These two distinct species have evolved the same structure for the same function. It can also occur at the functional level without structure, as exemplified by flight in birds, pterosaurs, and bats (Seed et al. 2009). Lastly, convergent evolution can also be observed in behavior and cognition. Differing species of birds, bank swallows and gulls, exhibit mobbing behavior as an antipredator defense (Sordahl 2004). Sociality in large-brained mammals and corvids also presents interesting selection pressures allowing for cultural transmission of dialects and tool use along with social intelligence (Marino 2002; Van Horik et al. 2012). Convergent evolution is a comparative method that can be used to examine similar traits across a variety of different lineages and can help the understanding of the different or similar selection pressures species have faced over their evolutionary history.

## Synonyms

Male sexual refractory period; Parental investment theory; Sperm competition

## Definition

A phenomenon occurring in the males of some sexually reproducing species wherein post-copulatory sexual arousal may be reignited if the male is presented with new sexual partners.

The Coolidge effect is a phenomenon observed in some sexually reproducing animals in which sexual arousal is reignited by novel sexual stimuli. The term was first coined by Frank A. Beach (Beach and Jordan 1956) and refers to a story involving US President Calvin Coolidge and his wife.

After completing sexual intercourse with a female, males will often experience a refractory period, during which they are unable to engage in sexual activity. One evolutionary explanation for the refractory period is that it prevents males from displacing their own semen from the female's reproductive tract. Another proposed adaptive benefit of the Coolidge effect is that it allows males to copulate with a new female more quickly after finishing copulation with a previous female, as the male does not risk displacing his own semen from the new female.

The Coolidge effect has been observed in a number of species. The first instance of this effect was observed in rats (Beach and Jordan 1956) and has been confirmed in more recent research which showed that, in addition to a shortened refractory period, male rats presented with novel sexual stimuli showed increased dopaminergic activity in the nucleus accumbens (Fiorino et al. 1997). This effect has also been observed in non-mammalian species such as fish (Jordan and Brooks 2010), invertebrates (Steiger et al. 2008), and hermaphroditic pond snails adopting the male role during copulation (Koene and Ter Maat 2007).

The Coolidge effect may also extend to differential sperm allocation. Research has found evidence that males of some species, such as European bitterlings, will allocate sperm differentially, such that males will produce higher-quality ejaculates during copulation with novel females than with familiar females (Pizzari et al. 2003; Spence et al. 2013). Because males have lower obligate parental investment to produce offspring to reproductive maturity than females, males possess adaptations for gaining sexual access to females. The Coolidge effect and the differential allocation of sperm to novel females are examples of adaptations that facilitate male mating.

Some evidence for the Coolidge effect has also been observed in humans. For example, one study investigated sex differences in the desire for sexual variety and found that, across cultures, men reported desire for a greater number of different sexual partners than did women (Schmitt 2003). In a more recent study, men more than women expressed a greater preference for a variety of sexual partners, regardless of the target's attractiveness (Hughes et al. 2020). The same study also reported that men more than women have a stronger preference for their partner to frequently change their physical appearance, whereas women more than men reported changing their own appearance more frequently. The results of this study suggest not only that men have a preference for sexual variety but also that women may be attuned to this preference.

While females may maximize their genetic success by enforcing their ability to choose high-quality mating partners, males may often maximize their genetic success by gaining sexual access to as many partners as possible. The Coolidge effect is one way in which males of some species are adapted to copulate with a large number of females.

## Definition

“The voluntary acting together of two or more individuals that brings about, or could potentially bring about, an end situation that benefits one, both, or all of them in a way that could not have

been brought about individually.” (Brosnan and de Waal 2002).

## Introduction

Cooperation is prevalent in a wide array of species and contexts. In humans, cooperation spans diverse situations from childhood play to government lawmaking. Cooperation is also seen in a wide variety of organisms, from plants to micro-organisms – such as bacteria and fungi – to megafauna. Certain species engage in complex cooperation in which individuals take on different roles, such as group hunting in chimpanzees and lions. Cooperation also occurs between animals of different species.

Historically, cooperation was largely understudied, likely for two reasons. First, the focus of animal behavior was the “nature red in tooth and claw” view that derived from our understanding that evolution was driven by individual benefits (Brosnan 2011); if was the case, why would individuals ever work together and risk benefitting another individual? This view assumed that cooperation was often evolutionarily disadvantageous and led to a widespread belief that there could not be much cooperation in the animal kingdom. Second, much animal behavior research took place in relatively easy environments, in which animals often can acquire what they need on their own. Biologists studying animals in more extreme environments, such as the tundra in Siberia, made the case that there were situations in which animals could not survive without working together and that cooperation was far more widespread than had been recognized (Kropotkin 1902). More recently, research has focused on the ways in which individuals do benefit themselves by working together, providing a solution to the apparent paradox of working together in a situation that rewards individual fitness (West et al. 2007).

There are several important factors to consider when trying to understand any behavior from an evolutionary perspective. At the most basic, there are two key features, the ultimate and proximate mechanisms. Ultimate mechanisms explain *why* individuals exhibit a behavior (i.e., what function

it plays for the animals), while proximate mechanisms explain *how* individuals exhibit a behavior (how that behavior is acquired and how it manifests). Tinbergen (1963) focused on four specific questions; understanding the ultimate mechanisms of behavior requires investigating the behavior’s phylogeny, or how the trait has evolved, and the behavior’s adaptive value, or how a behavior contributes to an individual’s reproductive fitness. Understanding the proximate mechanisms requires investigating the mechanistic explanations, or the physiology involved in a behavior, and the ontology, or how a behavior develops over an individual’s lifetime.

When studying any trait, it is crucial to distinguish between ultimate and proximate processes to avoid two key errors. First, confusing the two may lead to counterproductive debates about which explanation is “right” when in fact both explanations contribute to a full understanding by answering different questions about the trait. Moreover, different traits can share a function, but not a mechanism, or the reverse, so it is critical not to assume one from the other. For example, two behaviors may share the same function, but do so as a result of entirely different mechanisms; evolution can only work with the variation at hand, so a sufficiently important trait can evolve in different ways (for instance, insect and bird wings serve the same function, but the mechanics are quite different). In this case, assuming the same mechanisms is misleading. Similarly, having the same underlying mechanism does not guarantee the same functional outcome, because species differ in their selective pressures; to continue our example, penguins have wings, but they function in swimming, not flight (a case of divergence). Therefore, failing to separate ultimate and proximate mechanisms may potentially lead to inappropriate assumptions and conclusions.

In this entry, we first outline the approaches to cooperation. We then examine the ultimate explanations for cooperation, followed by the proximate mechanisms, including psychological, cognitive, and hormonal mechanisms. We then review the methods of studying cooperation and end by addressing the limits and potential of cooperation research.

## Four Approaches to Studying Cooperation

Cooperation is a broad topic, studied in a variety of fields, and each of these fields has developed its own terminology and approach. Bshary and Bergmüller (2008) outline four fundamental approaches: the basic social evolution theory, the ecological approach, the strategic approach, and the social scientists' approach. All overlap in some aspects and differ in others. To provide background, we first outline Bshary and Bergmüller's categorizations.

First, the basic social evolution approach explains cooperation in terms of its function. While there had been quite a lot of debate over the presence and adaptive value of altruism, this approach suggests that helping behavior more generally (i.e., minus the stringent assumptions of altruism) is selected for because cooperation increases inclusive fitness, which is a combination of direct fitness, through direct descendants (i.e., offspring), and indirect fitness through benefits provided to nonlinear kin. Sociobiological research has investigated the functional significance of behaviors such as parent-offspring conflict, differences in parental investment of sons and daughters, and female mate selection. The social evolution approach addresses what behaviors are selected for to directly or indirectly improve an individual's fitness.

Second, the ecological approach asserts that cooperation occurs when it is necessitated by an individual's social and/or ecological environment. While the social evolution approach focuses on the genetic influences of behavior, the ecological approach emphasizes environmental influences of behavior. Some environments are sufficiently extreme that cooperation is nearly a necessity. Moreover, in social groups there will be conflicts, which can be costly even to the winner of a competition. Cooperation can help individuals work together to avoid some of this conflict. Researchers in the ecological approach focus on environmental constraints such as food fluctuation and social constraints such as group size, group cohesion, or sex ratio. Much like the social evolution approach, the ecological

approach focuses on the benefits of inclusive fitness. However, it differs in its assertion that cooperation stems from social and ecological factors and that, unlike more rigid genetic influence considered in sociobiology, behavior may change as an individual develops or as environmental changes occur.

The third approach concentrates on how strategic decision-making evolved, which can be examined through average costs and benefits, such as those described in game theory. In this case, the mechanisms for cooperation include punishment, rewards, switching partners, and ending exchanges (Bshary and Bergmüller 2008). Unlike the first two approaches, the strategies approach takes into consideration the fact that individuals may alter decisions on a case-by-case basis based on previous interactions. An individual with high strategic and decision-making skills will be more apt to cooperate in a manner that will benefit themselves and will stop cooperating when exchanges result in a net loss. By maximizing benefit, and minimizing cost, an individual increases their fitness. Bshary and Bergmüller (2008) clarify that these strategies or decisions do not necessarily need to be conscious but can also be genetically determined.

Fourth, the social scientists' approach is the most exclusive of the approaches, as it only considers human cooperation. It argues that humans are unique due to complex abilities that influence our decisions, such as emotion, language, and moral judgment. According to this approach, these abilities enable humans to navigate situations in which we may or may not cooperate, including interactions with unrelated individuals or with significantly delayed rewards. Furthermore, it suggests that moral judgment provides a mechanism for human cooperation, as it is psychologically rewarding to help other cooperative individuals and to punish cheaters (Bshary and Bergmüller 2008). This approach does not address cooperative abilities in non-human species and emphasizes discontinuity – presumably due to a difference in cognitive abilities – between human and other animals. As a result, it is not particularly useful for understanding how cooperation evolved across species.

Although different fields of study may show preferences among the approaches, it is important to note that these approaches are not mutually exclusive; rather, they provide a framework to understand how cooperation has been studied. We focus on the strategic approach, as the emphasis on costs and benefits provides measurable outcomes of behavior. Additionally, we think it is important to consider the flexibility in behavioral responses, including responses across an array of social and ecological conditions, as well as how an individual may change their strategy within series of interactions with a partner, such that it explicitly incorporates the ideas of the other approaches.

## Key Hypotheses for the Evolution of Cooperative Behavior

Why would animals cooperate? The scientific literature offers four hypotheses: mutualism, kin selection, group selection, and reciprocity. Below, we discuss each of these, including psychological, cognitive, and hormonal mechanisms, and discuss specific behaviors that are hypothesized to be examples of each.

### Mutualism

Mutualism has unfortunately developed two somewhat different meanings. First is a relationship in which two or more individuals work together toward a common goal, and second occurs when individuals inadvertently benefit from the activity of the other (Dugatkin 1997). In the first case, if the individuals intentionally cooperate to achieve that mutual benefit, this likely requires at least a basic understanding of how the interaction will result in a reward. However, intentionality is not necessary for mutualism to occur. The second form of mutualism, known as by-product mutualism, is the most straightforward of the hypothesized mechanisms for cooperation as it requires no special understanding on the part of any of the individuals; each is working for their own benefit and incidentally benefits another individual in the process. As this requires no real explanation for how it would have evolved, in this entry we focus on the former.

In order for mutualism to occur, there needs to be a common enemy, or an adverse environmental factor that creates a situation in which two individuals will each benefit through cooperative behavior (Dugatkin 1997). This may occur between two or more conspecifics or may involve cooperation between members of different species, called interchange, or interspecific mutualism. Lions show intraspecific mutualism; individuals hunt alone when trying to kill small prey, and lions cooperate by hunting together for large prey, as larger groups are more successful. In this case, the lions cooperate by forming hunting groups, and all benefit when the prey is caught. A common example of interspecific mutualism is avian species “cleaning” ungulate species. The bird gets easy access to food, in the form of insects on the ungulate, and the ungulate benefits by having insects removed from its body. While neither animal has set out to help the other, both benefit through this interaction.

### Kin Selection

Kin selection describes the situation in which individuals provide a benefit to kin that their kin could not have obtained on their own. The ultimate explanation for this is that, since relatives share a proportion of their genetic material, benefitting a relative indirectly benefits one's own genes, a process called inclusive fitness. This focuses on the gene as the relevant unit of selection, rather than the organism, as it is the gene that receives the benefits when kin – who share those genes – are helped. Hamilton (1964) explained this through a simple equation known as Hamilton's rule:  $rB > C$ , in which  $r$  is the degree of relatedness between an individual and their kin,  $B$  is the benefit to their kin (the increase of offspring resulting from the helpful act), and  $C$  is the cost to the individual's reproductive fitness. As long as the product of the degree of relatedness and the benefit to the kin is greater than the cost to the individual, it is beneficial (for one's genes) to that individual to help their kin. As with mutualism, the individual does not consciously calculate this benefit, but rather the benefits and consequences of actions will eventually lead to these helping behaviors to be selected for

or against. It is important to note that kin selection emphasizes benefits that are beyond what the individual could have done on their own; for instance, helping with offspring care is only relevant to kin selection if the individual's help increases the number of surviving offspring beyond what would have been true without that help. This crucial component of kin selection is frequently overlooked, potentially resulting in the over-assumption of kin selection as motivating behavior.

Kin selection requires several mechanisms. First is kin recognition: an individual must be able to recognize their relatives, so that they direct their beneficial behavior toward relatives rather than unrelated members of a social group. This can be done through a variety of mechanisms, including familiarity (i.e., from being raised in the same nest) or phenotype matching, in which subjects match the look, sound, smell, or taste of another to their own and identify them as kin (although they need not understand this, it results in changed behavior for kin vs nonkin). Some species are not only able to recognize their own kin but are also able to recognize the familial relationships among others. For instance, when experiencing aggression from conspecifics, vervets and macaques frequently redirect aggression toward an opposing individual's relatives, suggesting that they have an understanding of the familial relationships between their opponent and other members of the group (Cheney 2011). Additionally, the individual must have opportunities repeatedly interact with the same kin.

### Group Selection

Although the use of group selection to explain the evolution of cooperation has been largely criticized, it remains a potentially important factor when studying cooperative behavior. For group selection to occur, multiple groups must display differences in trait-group productivity (Dugatkin 1997). While this argument is plausible in theory (Levin and Kilmer 1974), the reality is that the conditions necessary for group selection to transpire are so rigid that it is unlikely for it to occur regularly in animal populations. The exception, however, is group selection within humans.

Richerson et al. (2010) proposed that cultural evolution has been instrumental in human evolution through gene-culture evolution. While the selective pressures associated with human cultural changes may play an important role in our evolution, these group-level changes are likely of minimal impact in other animal species. Of note for this paper, there has also been controversy surrounding whether kin selection is merely a form of group selection (Nowak et al. 2010). This assertion was met with uproarious opposition within the field. Clearly, a great deal of controversy surrounding group selection remains.

### Reciprocity

In reciprocity, individuals trade favors and both ultimately benefit from the interactions. This is the mechanism about which perhaps the most has been written, in large part due to the variety of ways in which reciprocity can occur and the challenges in finding evidence for it. Robert Trivers originally recognized that individuals could benefit over the long term through the use of short-term exchanges to benefit one another. Specifically, he proposed reciprocal altruism, in which individuals take turns paying a cost to benefit the other; despite the short-term cost, the behavior will be selected for as long as the individual benefits in the long term (Trivers 1971). The idea was met enthusiastically, and many early studies searched for examples of reciprocal altruism in animals.

It has been trickier than expected to find them, however, at least in part due to the difficulty in quantifying costs and benefits. In addition, reciprocal altruism has high cognitive demands, as subjects must remember with whom they have interacted, keep track of favors given and received, and interact sufficiently often over a long enough lifespan that there is a reasonable chance that a favor will be returned in the future. Indeed, most of the studies purporting to show reciprocal altruism have been challenged with alternative explanations for the observed behaviors. Female vampire bats showed what was thought to be long-term, high-cost reciprocal altruism through blood sharing with conspecifics in need of food (Wilkinson 1984). However,

alternative explanations posit that these interactions may actually result from lower cost forms of reciprocity and/or kin selection, rather than reciprocal altruism.

Beyond these cognitive constraints, if subjects are exchanging different goods and services, such as grooming for food or support, how does one demonstrate that they are being traded? In most cases, scientists have either focused on a specific market or set up experimental markets in the lab. Even the latter, however, suffer from the problem that we do not know if the animals see exchanges as part of a market, and of course, even if they do, that market is still embedded within their larger social framework. Additionally, individuals may place different values on goods due to variation in need, making it difficult to calculate the subjectively perceived benefit for each individual. Finally, in most studies, whether wild or captive, scientists measure costs and benefits over a set, and often very short, time frame. However, reciprocal altruism may occur over a fairly long time span, up to years for some long-lived species. As a result, a study investigating reciprocal altruism, especially for long-lived animals, may simply not record data for a long enough duration to adequately capture reciprocal exchanges. Nonetheless, evidence continues to indicate that something of a reciprocal nature occurs.

More recently, scientists have expanded the idea of reciprocal altruism to include less cognitively demanding forms of reciprocity (although this does not circumvent all of the above problems). For example, Brosnan and de Waal (2002) outlined three categories: symmetry-based reciprocity, attitudinal reciprocity, and calculated reciprocity. Symmetry-based reciprocity is the simplest, requiring no additional cognitive ability, and is noncontingent. It is important to note that symmetry-based reciprocity is *functionally* reciprocity, but the underlying mechanism is not reciprocal, per se. Instead, the reciprocal interaction is based on symmetrical aspects of the relationships between individuals (based on age, social status, etc.) that lead to the same individuals to interact repeatedly. In short, if each individual is inclined to provide benefits (i.e., groom) and is indifferent to whom those benefits go, they are more likely, by definition, to provide them to

those with whom they spend a lot of time, for instance, because they are similar in rank or in the same family. Given the symmetrical nature of relationships, the partner will do the same. Thus, the key is that reciprocity occurs due to repeated interactions with the same individual, even if those involved are not seeking opportunities to do so and do not have any intention of being reciprocal. It is likely that quite a lot of reciprocity is based on symmetry in the relationship, even in species that have the cognitive capacity to engage in intentional reciprocity and are known to do so in other contexts. Nonetheless, recent modeling efforts indicate that symmetry of relationships alone may not be sufficient to support large-scale reciprocity.

Attitudinal reciprocity is contingent but does not require keeping track of individual interactions, nor is it intentional. In attitudinal reciprocity, the reciprocity is based on the fact that when one individual benefits another, the benefitted individual will have a positive attitude toward the donor. This makes the benefitted individual more likely to provide a benefit back to the donor within a relatively short time span. This requires a minimal amount of memory, as all that is needed is for the individuals to develop a positive feeling for the donor, and is likely to be emotionally mediated (Schino and Aureli 2010). As in symmetry-based reciprocity, attitudinal reciprocity requires repeated interactions with the same individual. However, it also requires recognizing that individual, as it is contingent on associating a positive feeling with a particular conspecific. Individual recognition is widespread across the animal kingdom, so this could be a widespread mechanism for reciprocity.

One of the best examples of attitudinal reciprocity comes from a study of captive chimpanzees exploring how grooming early in the day influenced food sharing later (de Waal 1997). Most experimental studies focus on the exchange of the same commodity, provided by the experimenter, over a very short time span (typically minutes). For the food sharing, de Waal used bundles of browse, a monopolizeable but nonetheless easily shareable food (sharing studies based on foods that chimpanzees can instantly consume, such as nuts or small fruits, rarely result

in sharing, presumably at least in part because the chimpanzees eat them too quickly). De Waal found that chimpanzees who had been groomed by another individual in the morning were more likely to share their food later on in the day and that it was specific to the individual who had groomed them; sharing did not increase toward individuals who had not groomed them. This suggests that the chimpanzees recognized a specific individual, remembered information about previous interactions with that individual, formed a positive association, and reciprocated at a later time. More intriguingly, more food was shared to individuals who did not frequently groom than those that did, suggesting that the chimpanzees not only remembered the morning's interactions but also how they related to their ongoing relationships. Finally, the chimpanzees were more likely to protest food-sharing requests made by an individual that had not previously groomed them. These results suggest contingent exchange with explicit memory for both short- and long-term relationships. This study highlights the need for experiments based on commodities that are naturally exchanged by the animals being studied, over time spans relevant to those animals.

Calculated reciprocity is the most complex form of reciprocity, as it involves contingency, the most cognitive ability, and intentionality; individuals explicitly trade commodities in a one-to-one fashion. In this, it is closest to Triver's formulation of reciprocal altruism. This form of reciprocity not only requires repeated interactions with the same individual but also recognizing them, as well as a host of cognitive features, hypothesized to include numerosity, low temporal discounting (so that they can inhibit taking an immediate reward), inhibition, the memory to remember others' reputations and the current tally of services, and the detection of cheaters. Stevens and Hauser (2004) argue that, while theoretically compelling, instances in which animals meticulously calculate the costs and benefits of every interaction are likely rare, as the cognitive requirements are simply too high. While large-brained social species may have the capacity to engage in calculated reciprocity, no evidence has been found that can completely eliminate the other forms of reciprocity. One exception to this

is humans, who have the cognitive capacity to engage in calculated reciprocity. However, while humans certainly can do so, it is likely that much reciprocity is still based on attitudes or even symmetrical aspects of the relationship.

Regardless of the type of reciprocity, there are a number of factors that must be considered. First commodities may include both goods, such as food items, and services, such as grooming or protection. While experiments often look at the exchange of goods, reciprocity in the wild quite often involves services, and it seems likely that cooperation evolved in the context of services. In comparison to goods, services are cheaper, are not limited resources, and are more difficult to take through coercion. For example, meat can be stolen, but it is very difficult to force an individual to groom you. In addition, the meat likely required substantial time and effort to obtain, whereas grooming can require minimal time and effort (depending on the length of the bout). Finally, goods are often zero-sum; if I share meat with you, I cannot share it with someone else, whereas services can, within limits, be provided to nearly anyone. This difference may also explain some of the difficulty in finding evidence of reciprocity in captive studies, which rely on goods (usually food) to motivate behavior.

Finally, while theory and experiments often focus on one-on-one exchanges, which are easier to quantify and track, reciprocity may function within a wider marketplace involving many simultaneous interactions among multiple individuals. This was formalized with the concept of the biological market, in which goods and services are exchanged and the "price" varies depending on the current supply and demand (Noë and Hammerstein 1994). In principle, this can also lead to indirect reciprocity, in which individuals may provide services to one individual but receive benefits from another.

## Mechanisms and Related Behaviors

Cooperation is supported by a variety of mechanisms. Of course, not all of these are required for each type of cooperation, nor do all individuals show them in each case. However, there are

sufficient consistencies across different types of cooperation that we consider them together. The exception may be by-product mutualism; as the cooperative outcome is simply a by-product of individuals pursuing their own best interests, few, if any, distinctive mechanisms are required.

### **Prosocial Behavior**

Prosocial behavior, or behavior that provides a benefit to another, has been observed in numerous animal species. Such helping behavior is often contingent on the identity of the actors and the circumstances. For instance, rats help conspecifics and are more likely to help individuals who have previously assisted them compared to those who have not (Rutte and Taborsky 2008). Evidence in primates is far more mixed, for reasons that are not entirely clear. Certainly, context has something to do with it, and there is growing evidence that primates may not understand the purpose of the tasks that we give them or may be disinclined to provide benefit unless there is a reason to do so.

It is important to note that prosocial behavior is distinct from altruism in that it is specifically the provision of benefit, with no assumptions about the costs to the actor. In addition, as with all behaviors, it is critical to distinguish between behavior that functions prosocially – providing a benefit to another – and prosocial motivations. The examples we discussed above are all the former, but not necessarily the latter. For a more detailed discussion of prosocial behavior, see the entry in this encyclopedia (Sosnowski & Brosnan).

### **Empathy**

Empathy is the understanding of another's feelings and goals and allows individuals to metaphorically step into another's shoes. Clearly this would be beneficial for cooperation as it provides a means to determine what the other needs. Whether animals actually have a capacity for empathy is hotly debated. On the one hand, there are ample anecdotes of behavior that appears empathetic, such as helping individuals obtain a food that is out of reach, but it is difficult to draw conclusions from these anecdotes, and while such "positive" occurrences are noted and

reported, it is unknown how many instances in which an animal could have helped and did not go unnoticed and unreported. Because of this, there is an emerging focus on studies that can provide more systematic evidence. For example, based on the fact that contagious yawning is absent in humans who are on the autism spectrum, it has been argued that contagious yawning is a sign of at least a basic form of empathy, although this relationship remains controversial. Rats, primates, and humans all exhibit yawn contagion in the presence of members of their social group, but not strangers. There is also evidence that chimpanzees, but not monkeys, console the victims of aggression, although, yet again, the degree to which this is due to empathy for the victim, rather than to calm the stress of the intervening bystander, is debated.

Some of the best evidence for empathy comes from studies exploring how individuals react when their partners are in pain, for instance, from receiving a mild shock or being trapped. Evidence from rats and mice shows a strong tendency for observers to act to help the distressed rat, and mice receiving a foot shock respond with even more pain if observing a conspecific get a shock as well, suggesting contagion. Studies from the middle of the last century provide similar results in primates, although there have been no recent studies using these methods. These results, which show more consistent findings suggestive of empathy than the prosocial studies mentioned above, suggest that empathy may be more commonly evoked in high-valence situations, possibly in particular involving pain and distress, than in the relatively low valence food-sharing situations. However, a different interpretation is that the empathetic bystanders are actually acting to reduce their own distress, either at the situation or to cease the stressful fear and alarm calls of their companion. As with many of these topics, the degree to which other species show evidence of empathy is still up for debate.

### **Inequity and Cooperation**

Several species, including primates, canids, corvids, and rats, respond negatively to getting less than a social partner. Such inequity responses

may facilitate cooperation by giving individuals a way to determine whether they are benefitting from a cooperative partnership; if rewards are equal, they should continue to participate, but if their partner consistently gets better rewards, it is time to find a new cooperative partner (Brosnan and de Waal 2014). This hypothesis, first proposed in economics, draws comparative support from two main lines of evidence. First, cooperation and inequity appear to be related at the phylogenetic level, as more cooperative species are also those most likely to respond negatively to inequity. Second, at the individual level, inequity can disrupt cooperation. For example, capuchin monkeys, who both cooperate extensively and show marked responses to inequity, cease cooperating when rewards are clumped so that they are monopolizable by one of the two subjects. Indeed, they do this from the first trial, indicating that they understand the potential outcome when rewards are clumped, and this is true for both nonkin and kin pairs. However, this may be as much due to the partner's behavior as the potential outcomes. When rewards are not monopolizable, but are unequal, cooperation is successful despite the inequity as long as subjects take turns receiving the better reward. In partnerships in which one individual dominates the better reward, cooperation drops, even in trials in which unequal rewards are impossible. Together these results suggest that cooperation and a response to inequity have coevolved and that this relationship is relatively widespread, at least among vertebrates.

To what degree, however, should inequity impact cooperation? In the case of mutualism, inequity should be irrelevant because subjects are incidentally providing the benefit to their partner in order to benefit themselves; therefore, the partner's outcome is uninformative as they are not actively helping, and there is no need to judge their value as a partner. Similarly, inequity may not be terribly relevant in kin selection; as long as the individual helping their relative is gaining more in inclusive fitness than they are paying in cost, they should cooperate. There may be situations in which one helper is providing more than another, but even in this case, if it benefits the

actor to continue helping, they should do so. Inequity should be highly relevant in direct reciprocity and biological markets, in which individuals stand to lose substantially if others are benefitting more than they are and can exercise their choice and find a new partner if the current one is not providing sufficient benefit. Finally, inequity may be far less important in indirect reciprocity, as there is no direct partner to "cheat," except if there are reputation effects; if subjects' reputations are impacted by their cooperative tendency, inequity will again be highly relevant as a marker for a non-cooperative individual. Indeed, the presence of strong inequity aversion in humans may explain why reputation effects are so much stronger in humans than other species; they provide a mechanism to detect cheaters who would otherwise render indirect reciprocity too costly (Brosnan and Bshary 2016).

In all of these cases, subjects should not respond too quickly to inequalities. It is the rare interaction that is always perfectly equally beneficial to all parties, and responding to any inequality by finding a new partner risks losing a successful cooperative relationship (in which subjects take turns being the more benefitted) over what may have been either a normal part of the relationship or an accident. Data from capuchins implies that they do not respond to every inequality but can successfully cooperate through short-term inequalities as long as the long-term relationship is balanced (reviewed in Brosnan 2011). If inequality persists over a longer duration of time, however, an individual's aversion to inequity should cause them to suspend cooperation to avoid uncooperative partners (Cheney 2011; Brosnan 2011).

### Hormonal Mechanisms of Cooperation

Hormones are key drivers of behavior, including cooperation (Soares et al. 2010), and there is a reciprocal relationship such that hormones may influence behavior and behavior may influence hormones. One key hormone is oxytocin, which has been shown to play a role in forming and sustaining social relationships, such as mother-infant bonds, pair-bonds, and friendships. Studies have implicated oxytocin in everything from the

formation of memories related to social interactions to individual recognition, to more trusting and cooperative behavior in economic game experiments (Bartz et al. 2011). There is also evidence that oxytocin is linked to the neurotransmitters associated with the brain's reward systems, including serotonin and dopamine, suggesting that social interactions are literally rewarding. As a result, the benefits of social interactions may ultimately lead to long-term social relationships (Soares et al. 2010). Despite these benefits, however, other evidence suggests that the relationship is more complex. For instance, while oxytocin often promotes in-group cooperation, it also leads to less *out*-group cooperation. In addition, a growing number of studies find no effect of the hormone, especially with exogenously administered oxytocin. The effects of oxytocin are complicated, with results influenced by individual, social, and contextual factors and, it appears, whether the oxytocin was endogenous or was exogenously administered.

Testosterone also influences cooperation in complex ways. When males experience testosterone increases in preparation for breeding, they may become less cooperative and more competitive. Conversely, this spike in testosterone may also facilitate pair-bonding and play a role in cooperative tasks such as group territory defense, suggesting that the change may be dependent on the relationship between individuals (Soares et al. 2010). According to the "Dual Hormone Hypothesis," the effects of testosterone are contingent on the presence of another hormone, cortisol. For example, there is a positive correlation between testosterone and cortisol in individuals that exhibit low levels of cortisol. In the presence of high cortisol levels, however, this relationship between the hormones is absent (Mehta and Josephs 2010). Research in humans suggests that cortisol may also play a part in the relationship between testosterone and cooperation.

## Measuring Cooperation

Cooperation occurs across a variety of different contexts. It is seen in the field in naturally

occurring contexts as well as in experimental paradigms that have been used to better understand underlying mechanisms, largely in lab settings. Both are key to fully understand why animals cooperate as well as when, how, with whom, and in what contexts they do so.

## Field Studies

Most field studies are necessarily observational, with researchers documenting cooperative behaviors such as group hunting, territory defense, coalitions, and predator defense. Considering the first of these, group hunting is seen in a variety of species and contexts, ranging from individuals opportunistically chasing the same prey item at the same time to active coordination by multiple individuals with differing roles. Chimpanzees in the Tâi Forest in Côte d'Ivoire show such complex coordination, in which individuals perform different roles in the hunt, are more successful in groups than alone, and are thought to share the prey afterward based on participation more than existing coalitions and alliances. Over the course of their lifetime, the chimpanzee takes on a series of increasingly difficult roles in the hunt as they gain experience. The skills required to successfully hunt as part of the group are sufficiently complex that it often takes 20 years of practice to be consistently successful (Boesch 2002). Intriguingly, not all chimpanzees show such complex hunts; chimpanzees in Gombe National Forest primarily hunt alone and share meat based on their current alliances. One hypothesis for this difference is that the continuous tree cover at Tâi necessitates cooperation because the monkeys can escape so easily, whereas the fragmented canopy at Gombe means that monkeys can be cornered, obviating the need for cooperation (Boesch 2002). If true, this points to the importance of understanding ecology for determining when cooperation will evolve; cooperation may be unlikely, even in species that have the cognitive capacity for it, if it is not needed.

These coordinated hunts are also seen outside of the primates. Emphasizing that cooperation does not require mammalian cognition, Harris' hawks also utilize multiple group hunting tactics, including taking turns chasing a rabbit until the

rabbit becomes exhausted and, consequently, slow enough to catch (Bednarz 1988). In this case, individuals cooperate by taking turns rather than simultaneously playing different roles like those seen in chimpanzees, but similarly to the chimpanzees, the hawks are unlikely to be able to complete the hunt on their own. Coordinated cooperation may also occur between species; recently it was discovered the grouper and giant moray eels are coordinating hunting, with grouper actively signaling specific moray eel in order to begin a coordinated hunt (Bshary et al. 2006).

In some situations, cooperation and conflict coexist within the same interaction. For example, many species show coordinated defense of the group territory. However, in some birds, social groups compete with one another for territory, only to then switch to cooperation by respecting the opposing group's boundaries. This phenomenon, known as the "Dear Enemy" effect, allows the birds to coexist without needing to constantly renegotiate group boundaries through potentially costly conflict (Dugatkin 1997). Similarly, animals routinely form coalitions or alliances to acquire or maintain rank or mating opportunities. In some cases, these relationships are unambiguously cooperative, as when male dolphins form long-term alliances despite the fact that one male will likely monopolize mating opportunities. Even within relationships, however, there will be elements of cooperation and conflict. Frans de Waal, in his book *Chimpanzee Politics*, outlined a complex relationship between two male chimpanzees who formed a coalition that allowed them to maintain dominance over a younger male, but still occasionally competed (de Waal 2007). Ultimately competition broke apart their alliance and allowed the younger male to assume the alpha position.

### Experimental Paradigms

Controlled experiments allow us to consider different factors that influence cooperation and begin to unravel causal connections, potentially providing more insight into the motives involved. One commonly used experimental apparatus is a bar-pulling mechanism, in which subjects must work together to pull in a tray with food. This

can be done by counterweighting the tray so that multiple individuals are needed to pull it in, or by using a rope threaded through the tray with two exposed ends, so that if it is only pulled on one end, it comes unthreaded and it is then impossible to pull in the tray. Such tests typically involve a mutualism condition (both pull and both receive food) as well as solo controls, or conditions in which one side of the tray has a less preferred food, less food, or no food, to see how their willingness to cooperate is influenced by reward distribution. Experimenters can also use different social combinations to explore the role of kinship or relationship quality, allow subjects free access to come and go, or restrict subjects' ability to see one another (reviewed in Brosnan 2011). These studies have been widely used in primates, dogs, elephants, and birds, all of whom cooperate in at least some contexts. For instance, numerous studies in capuchins have uncovered that these monkeys do better when they can see their partner (presumably because they are visually coordinating) and are sensitive to the relative rewards, indicating that they understand the potential outcomes of the interaction for both them and their partner. Elephants will wait until their partner is released before attempting to use the barpull, indicating that they understand the need for a partner to complete the task.

This paradigm is extremely simple, intuitive, and flexible and has ecological validity (many species acquire food by pulling it toward them; think of pulling down a tree branch to reach a fruit hanging on it). This is probably one of the reasons why it has been so successful. Intriguingly, an apparently similar procedure that requires two individuals to simultaneously press a button in order to receive a joint reward has not been as successful. Capuchin monkeys who were very successful at the barpull were unable to coordinate on this task. The authors argue that it was both less ecologically relevant (monkeys do not press buttons in the field) and not intuitive for the subjects (due to the lack of obvious connection, to monkeys, between pushing the button and getting juice; Brosnan and de Waal 2002). One key advantage of the barpull is that it offers immediate kinesthetic feedback; on a

weighted barpull, if you let go, my side of the tray becomes immediately too heavy, and on the threaded string, if you pull first, my side of the string moves out of reach. This highlights, again, the importance of testing using multiple modalities in order to ensure that the animals are given a version of the task that is appropriate and comprehensible to them.

A second experimental approach to cooperation uses games derived from experimental economics. In these tasks, subjects make a choice between one of several options and are rewarded based on what both they and their partner choose. This allows for very complex decisions to be distilled down to simple, often dichotomous, choices and is flexible enough to use for multiple types of decisions (i.e., by changing payoffs). Most studies have either used a computerized version, in which subjects make choices between icons on a shared computer system, or a manual version, in which subjects return tokens or choose targets to make their choice. These designs are often modified versions of economic games used in human studies, such as the Assurance Game, the Hawk-Dove Game, and the Prisoner's Dilemma Game (Smith et al. 2018; see Smith & Brosnan entry on Coordination Games in this encyclopedia). Much like the bar-pulling task, these games can be adapted to meet the needs of several species, enabling taxonomically broad comparisons.

Such tasks have already been informative in understanding differences among species. One collaboration has compared the responses of humans, chimpanzees, rhesus monkeys, capuchin monkeys, and squirrel monkeys (Smith et al. 2018). They found, for example, that in a coordination game called the Assurance Game, members of all species could find the highest-paying coordinated outcome, but, emphasizing that outcome is not the same as mechanism, how they did so varied across species. For instance, capuchins appeared to simply match their partner, whereas chimpanzees and humans showed evidence of having an explicit strategy for the game. They also found evidence that context is important, as human subjects, not surprisingly, more often coordinated on the highest-paying

solution when they talked to one another, and chimpanzees with extensive experience in cognitive testing were more likely to find the coordinated outcome than those without such experience. Although these tasks are not terribly ecologically valid, they provide a good foundation for cross-species comparisons, and the results can be used to make predictions about how subjects will behave in more natural contexts, which allows for testing of the results of these models.

Finally, while the previous tasks are typically implemented with dyads, real-life social interactions take place within the context of the entire social group. There has been a recent push to explore the effect of the group setting on these decisions. In some cases, researchers are repeating the barpull and economic game studies in a group setting, to determine who chooses to pair together when they have free choice and to explore what strategies emerge in this more open system. Subjects also may be in situations in which their actions benefit others in their group, but not necessarily themselves (i.e., alarm calling). In the so-called group-service experiment, individuals are given the opportunity to provide food to their group without receiving any themselves. In a group-service experiment with Japanese macaques, capuchins, and common marmosets, only common marmosets consistently completed the task to provide food to their social group (Burkart and van Schaik 2013). This supports one hypothesis for the evolution of prosocial behavior, which is that it emerged in the context of cooperative breeding. Future research will be needed to determine how cooperation is linked to other behaviors, such as prosocial behavior, and is influenced by social system, ecology, relationship, etc.

Finally, we wish to reiterate the importance of experimental design. In designing an apparatus, it is crucial to cater the design to the physical and cognitive capabilities of the species being studied (Smith et al. 2018). The subject must be able to physically complete the task and understand the task in the way that the experimenter intended (i.e., not use one ability to solve the task when the researcher was measuring another). As mentioned previously, it is important to ensure that

the task design is, when possible, ecologically relevant and that it offers appropriate feedback. There is no perfect design. For example, while computer tasks may allow for more flexibility in how the task is presented, they are presumably less intuitive than manual tasks for these animals. In addition, computer tasks can offer an environment that enhances learning (i.e., shorter delay between choice and reward, fewer extraneous cues that might distract) but only, ironically, after a fairly extensive learning period for the animal being tested. It is also important to consider social issues potentially distracting the subject; pairing the lowest-ranking subject with the alpha male will likely result in a subject who does not participate at all. In any experiment, it is important to design appropriate controls to rule out alternate explanations and help better understand how the subjects are interpreting the task (i.e., solo controls or no food controls in barpull tasks tell us whether subjects are actively trying to get food or cooperate, or are simply pulling every time they see a barpull). Finally, for comparative work, it is key to utilize similar tasks; otherwise it is impossible to know whether the results were due to the animals' actual abilities or the differences in the task. This is likely exacerbated for studies comparing humans to other species; in this case, modified tasks should be "back tested" on humans to ensure that the modified task elicits the same behavior as expected based on the human-typical version of the task.

## Future Research

Studies on animal cooperation have proliferated in the last few decades, as scientists investigate how and why animals cooperate. There are a few obvious directions for work in the next decade. First, it is clear that we need a better understanding of how social dynamics influence cooperation. There has been a shift toward conducting group-oriented experiments, such as the group-service paradigm, rather than pair-based methodology, which is a good start. In group-oriented paradigms, subjects have the ability to choose a partner for cooperative tasks. This may reduce

the likelihood that they choose not to cooperate due to an objectionable partner as well as allowing us to better understand how cooperation is influenced by who is present. Do individuals make different responses when others can see them? Does it matter who they are, or what their rank is? Recent evidence indicates that personality is influencing decisions in a variety of contexts, so does the temperament of the observer matter? Do we find evidence for reputation or third party interaction in cooperative interactions? Finally, group settings allow individuals to make decisions as part of a group, providing a social context that may influence behaviors in a manner more closely resembling those in wild populations. Indeed, then, a key advance will be when we can more directly compare results in the lab with those in the field to bridge the gap between the two approaches.

Past research has predominantly focused on species that exhibit cooperative behavior in the wild, but there is also a need to study species that have not yet demonstrated such abilities. In the case of solitary species, individuals may have the capacity to cooperate but, due to their social structure, are not presented with the opportunity to do so in natural contexts. Indeed, many of these species will happily live in social settings in captive environments, such as zoos, so this allows us to test for behavior in captivity that will literally not occur in the wild. Understanding the degree to which cooperation is, or is not, limited to social species will help us not only better understand the more solitary species' social interactions but may also help disentangle features of cooperation that are explicitly social from those that are used in a wider variety of contexts including, when the opportunity presents itself, cooperative ones.

Finally, creating additional methodologies that more successfully accommodate subjects' physical and/or cognitive abilities may illuminate cooperative abilities that were previously thought to be lacking in various species. Indeed, they may also help with comparative work. At the moment, comparative paradigms are relatively artificial (i.e., economic games) because of the need for procedures that can be easily implemented and

understood across a variety of species, who may differ in cognitive ability, body plan, and sensory system. Ideally, the predictions derived from these comparisons are then back-checked using species-typical methodologies, but this can be supplemented with other data. For example, hormonal data collection has already been instrumental in this effort, as many hormones play a similar role in many species and, therefore, facilitate between- and within-species comparisons. Ultimately, better understanding how animals cooperate and what factors influence it across phylogeny and environment will help us better understand how our own cooperative behavior has evolved.

### Definition

Cooperative breeding is a reproductive system in which helpers – i.e., individuals other than the parents – cooperate to raise offspring and thereby increase the immatures' growth and survival. In obligate cooperative breeders, a breeding pair is incapable of rearing offspring without the support of helpers (i.e., alloparental care), whereas facultative cooperative breeders are also able to successfully raise offspring without alloparental care.

### Synonyms and Related Notions

*Allomaternal* care refers to care provided by any individual other than the mother – including the father – and thus also includes **biparental care**. *Alloparental* care refers to care provided by individuals other than the parents and includes cooperative breeding and **eusociality**. The latter is an extreme form of cooperative breeding in which some classes of individuals forgo independent reproduction (reproductive division of labor).

## General Description

Cooperative breeding has evolved in a variety of lineages including insects, fish, birds, and mammals. Helpers are often, but not always, close relatives of the immatures, such as older siblings, and can provide a broad variety of helping behaviors including fanning eggs, and predator defense, food provisioning, and infant carrying. Regardless of the type of alloparental care, this help is beneficial in that it increases infant growth and survival.

Obviously, each taxon has a distinctive set of infant care behaviors, according to its own biology. Birds incubate eggs and may provision fledglings, whereas in mammals, the most important care behavior is providing milk by mothers. Since not all caretaking behaviors are equally amenable to allomaternal care, the type of a species' infant care behavior contributes to the taxonomic distribution and evolutionary pathways that can lead to cooperative breeding. Most importantly, breastfeeding cannot be performed by males, and as a consequence, cooperative breeding is much more prevalent in birds compared to mammals (roughly 3% of mammals, and between 8% and 17% of bird species; Heinsohn and Double 2004). Isler and van Schaik (2012) provide a systematic overview of shared infant care behaviors and their distribution among mammals. The most prevalent are infant carrying (e.g., common marmoset; *Callithrix jacchus*); provisioning (e.g., wild dogs; *Lycaon pictus*), allonursing (e.g., meerkats, *Suricata suricatta*), protection (e.g., cotton-top tamarin; *Saguinus oedipus*), and thermoregulation/babysitting (e.g., banded mongoose; *Mungos mungo*), and they typically co-occur in cooperatively breeding species. In birds, shared offspring care typically includes incubating eggs (Seychelles warbler; *Acrocephalus sechellensis*), provisioning (Acorn woodpeckers; *Melanerpes formicivorus*), and protection (Siberian jays; *Perisoreus infaustus*). In extreme cases such as in social spiders – *Stegodyphus mimosarum* and *Stegodyphus dumicola* – helpers are consumed by the offspring even when they are unrelated to them (Lubin and Bilde 2007).

Due to the help that mothers receive in rearing their offspring, they can produce more, larger, or more closely spaced offspring than would be possible if they were alone responsible for raising them (Hrdy 2005). In cooperatively breeding callitrichid monkeys, for instance, females give birth to twins, which is unusual for primates, and exhibit a postpartum estrus which allows them to get pregnant again almost immediately after giving birth (Erb and Porter 2017). They can thus simultaneously be pregnant and lactating, and the next set of offspring is born when the previous one is still not fully independent. In immatures, cooperative breeding can lead to prolonged dependence, as for instance in birds where cooperative breeding is systematically related with post-fledgling nutritional dependence (Langen 2000).

Cooperatively breeding species are group-living, often with a high reproductive skew, i.e., some individuals reproduce far more offspring than others. This is the case in obligate cooperative breeders, where breeding positions are limited because of the obligate need of helpers to successfully reproduce.

Helpers can be close kin, and are very often older siblings, or non-kin, such as immigrants of either sex, or co-breeding males. When helpers are older siblings, cooperative breeding is typically associated with delayed dispersal (i.e., the act of leaving the natal group and moving to a different area in order to start a new group or immigrate into a neighboring group). Thus, helpers incur considerable costs because instead of leaving their natal group and starting their own reproductive careers, they stay with the parents and help rearing their younger siblings. However, under certain conditions, dispersal is difficult and it can be beneficial to delay it, e.g. because of habitat saturation (Schrader and Pillay 2005) or high predation risk (Heg et al. 2004). Habitat saturation refers to situations where due to high population density and/or to harsh environmental conditions, all suitable habitats are already occupied. It is often the cause for delaying dispersal in birds. Predation risk, on the other hand, can lead to delayed dispersal because of the safety in numbers effect, and has more often been linked to cooperative breeding in fish. When the cost of dispersal

is too high, due to either biological or ecological constraints, dispersal can be delayed for an indefinite period of time, and thus also own breeding attempts (Hatchwell 2009). Due to delayed dispersal, a cooperatively breeding group usually consists of a breeding pair, and several overlapping offspring generations living together (Cockburn 1998; Lukas and Clutton-Brock 2012). This organization leads to an increase in relatedness within a given group, making it easier for cooperative behaviors to become *evolutionarily stable strategies* (ESS).

## Evolutionary Pathways

Helping behavior has a cost and it will only be selected if the benefits, direct or indirect, outweigh these costs. For cooperative breeding to evolve, it is broadly accepted that kinship and thus indirect benefits play a crucial role: when helping to rear close relatives such as younger siblings, the costs for the helpers is offset by the benefits to the offspring, depending on the degree of relatedness, according to Hamilton's rule. Kinship and indirect benefits are thought to be crucial for the evolution of cooperative breeding, but their role appears not always essential to maintain helping behaviors because the link between relatedness and helping is often weaker than one would expect. Therefore, direct benefits often linked to group augmentation (i.e., that individuals survive and reproduce better in larger groups; Kokko et al. 2001) appear to play an important role too. Emlen et al. (1991) have compiled several nonexclusive hypotheses as to why animals may directly benefit from helping to rear offspring that are not their own. These hypotheses have been tested and supported in several different taxa so far, but it is becoming increasingly obvious that there is not a single general explanation but that the importance of these factors vary contingent on biological and ecological species-specific constraints (Hing et al. 2017). Their hypotheses are:

- Helping increases infant survival, and consequently, group size. The helper would benefit from group size effects.

- Helping as a condition of being allowed in the groups by the breeders (pay-to-stay). The helper would gain benefits through access to resources.
- Helping increases group size and therefore expands the natal area. The helper would use a portion of the territory to increase breeding probability in the future.
- Helping behavior facilitates social coalition formation. The helper and its coalition partners would outcompete other individuals for available breeding positions.
- Helping would increase the chances of a helper to be chosen as a mate by a breeder. This hypothesis would be applicable to species where mate availability is a limiting factor.
- Helping behavior increases parenting experience, raising the likelihood for infant survival when the helper becomes a breeder.
- Helping behavior towards an infant would make it more likely that this infant would become a future helper when there is a new breeding opportunity.

Cooperatively breeding species appeared several times throughout evolutionary time. Given the multiple possibilities that helping behavior could be naturally selected, together with varying constraints imposed by the specific types of care-taking behaviors, one can reasonably expect that the evolutionary pathways leading to cooperative breeding differ to some extent. Some major differences in these pathways appear present in birds vs. mammals (Burkart et al. 2017; Griesser et al. 2017; Lukas and Clutton-Brock 2013).

The evolutionary pathway for cooperative breeding in pair-living birds appears to follow a two steps scenario (Griesser et al. 2017). In pair-living birds, fathers typically provide offspring care, probably because incubating and provisioning can be performed as easily by the male as it can by the female. In a first step, family living evolved when offspring stayed with the parents beyond independence, most likely because the offspring benefits from staying with the parents in terms of predation avoidance and skill learning. Family living is associated with more productive and seasonal environments and is a critical

evolutionary stepping stone for cooperative breeding in birds. When delayed dispersal is long enough until the next breeding season begins, retained offspring typically start helping in rearing the next brood; in fact, having non-helping previous offspring around is very rare in birds, just as is having non-helping fathers around. This second step towards cooperative breeding in birds, i.e., that immatures delay dispersal beyond the next breeding season, is thought to be facilitated by environmental variability and the associated less predictable food supply.

In mammals, the situation is slightly different. First, pair-living is rarer and even when it is present, the males often do not contribute to infant care, most likely because breastfeeding is typically the most important infant care behavior and cannot be taken over by males. Second, the immatures often disperse late enough that they would have the opportunity to help raising their younger siblings, yet they don't. The first step towards cooperative breeding in pair-living mammals therefore was most likely that males started to provide infant care. As a consequence, females could increase their reproductive efforts, which in turn made it more profitable for older offspring to provide help in raising their younger siblings. As in birds, this final step was most likely facilitated by more variable food availability. In both cases – birds and mammals – harsh and variable environmental conditions and high average relatedness make it easier for alloparental behavior to be selected due to higher benefits from allocare, and indirect fitness, respectively (Griesser et al. 2017; Lukas and Clutton-Brock 2012).

## Cooperative Breeding and Its Consequences

At the behavioral level, competition for rare breeding positions can be fierce among cooperative breeders, but this appears not to translate to other domains. Rather, everyday life is often characterized by high social tolerance and prosociality, which are apparently necessary to facilitate smooth cooperation among group members on a daily basis. For instance, if infants are

carried by all group members, and directly handed over from one carrier to the next, constantly high levels of social tolerance among all group members are crucial to enable such close range behavioral coordination. These links between social tolerance and proactive prosociality are well established in primates (including comparative studies over a large number of species (Burkart et al. 2014; Schaffner and Caine 2000), and increasingly so in birds (Horn et al. 2016).

Even though helpers forgo independent reproduction, behavioral coercion is typically not involved in promoting helping (Finkenwirth and Burkart 2018). This is also mirrored in hormonal glucocorticoid levels, which are generally higher in breeders rather than helpers, both in mammals and birds (Creel 2001). Furthermore, among cooperatively breeding primates, oxytocin levels raise after the birth of a new infant not only in the mother but in all group members, which is linked to infant care behaviors (Finkenwirth et al. 2016), and also to proactive prosociality among adults (Finkenwirth and Burkart 2017).

These behavioral correlates of cooperative breeding can have implications for understanding human evolution (Burkart et al. 2009). Among primates, humans and callitrichid monkeys are the only cooperative breeders, whereas allomaternal care is notably absent in other great apes. Compared to great apes, humans can have more and more closely spaced offspring, despite longer periods of dependence. For instance, humans (hunter-gatherers; Marlowe 2005) compared to great apes (van Noordwijk et al. 2018) have much shorter birth intervals (3.5 vs. 5–9 years) and wean their offspring earlier (2.5 vs. 4–8 years), yet reach their age at first reproduction later (19.5 vs. 10–14 years). This unusual *life history* pattern is exactly what is expected for a cooperative breeder and contributes to understanding the demographic success of humans (Hrdy 2009).

As a result of the behavioral predispositions associated with cooperative breeding, such as social tolerance and proactive prosociality, cooperatively breeding primates tend to perform particularly well in sociocognitive domains such as

social learning, communication, or cooperative problem solving, whereas in nonsocial cognitive domains they show regular performance as expected for their brain size (Burkart and van Schaik 2016). Similar effects likely emerged in the human lineage as well, but since these consequences were added to a much more powerful cognitive system to start with, they could release cascading effects eventually resulting in a set of uniquely human psychological and cognitive traits (Burkart et al. 2009; Tomasello and Gonzalez-Cabrera 2017).

## Conclusion

Cooperative breeding is a reproductive system in which individuals other than parents help to raise offspring and has evolved in several lineages. From an evolutionary perspective, this behavior is surprising given that individuals that forgo individual reproduction and instead help others face obvious fitness costs. Nevertheless, cooperative breeding has convergently evolved in several lineages, and theories that incorporate both the costs and benefits of helping can now delineate the conditions under which such a system is likely to evolve. Importantly, in addition to indirect benefits that emanate from helping close kin, direct benefits also play an important role in explaining these theories.

Among mammals, allomaternal care is rare, with the exception of primates. In primates, allomaternal care is more widespread than in other mammals, but the only cooperatively breeding primates are callitrichid monkeys and humans. This convergence plays an important role in current theories of human evolution because of its implications for the emergence of demographic, life-history, and psychological human traits.

## Cooperative Hunting

Joy Vincent  
Oakland University, Rochester, MI, USA

### Synonyms

[Collaborative hunting](#); [Coordinated hunting](#)

### Definition

Cooperative hunting results from the coordination of group behaviors in such a way that increases the probability of a successful hunt, often of prey that are larger and able to be shared amongst those participating individuals.

### Cooperative Hunting

Cooperative hunting has been observed almost exclusively in social species, such as lions, killer whales, chimpanzees, and wolves (Bednarz 1988). Much of what is known about cooperative hunting and the conditions under which it evolves

in species sources from observations of the hunting practices of Tai chimpanzees (*Pan troglodytes*). Much of the following information derives from such observations, as this model species exhibits many hallmarks of cooperative hunting.

As cooperative hunting requires the participation of one or more individuals, there is an underlying need for cooperative hunters to exhibit social complexity. Four levels of increasing complexity characterize group-hunting. The lowest level of complexity, similarity, is characterized by individuals directing their behaviors at a single target; however, these actions lack temporal and spatial coordination. When the behaviors of the group align temporally, it is known as synchrony. Coordination represents a further increase in complexity as individuals relate their actions temporally and spatially to the actions of the other group members. Finally, the highest level of complexity is collaboration. When collaborating, individuals not only coordinate their behaviors, but also perform a variety of complementary behaviors directed at the same target (Boesch and Boesch 1989), which may require understanding the others' role in completing the goal.

The higher the level of complexity demonstrated by the group members, the increased likelihood that their hunt will be successful. Cooperative hunting yields a number of benefits for the individual group as well as their environment. The environmental disturbance from hunting is drastically decreased when hunting as a group, compared to when individuals hunt on their own (Estes and Goddard 1967). Cooperatively hunting allows individuals to take down larger prey than they otherwise would be able to when hunting alone. This increased yield for decreased energy expenditure is a central tenet of cooperative hunting (Estes and Goddard 1967). Having more individuals involved in the hunt aids in discouraging potential scavenging by other species following the kill. Hunting as a pack also allows for the protection of more vulnerable members of the group, such as mothers with young and those that are sick (Estes and Goddard 1967).

Given the plurality of benefits accrued from hunting cooperatively, it begs the question of why there are not more species that exhibit this method of hunting. There are two conditions under which cooperative hunting evolves in a society: the probability of success is low for a lone individual and there is some sort of deterrent in place that limits the access of cheaters to meat secured during the hunt (Boesch 1994; Stander 1992). The distribution of meat is central to the evolutionary stability of cooperative hunting; if there is no increase in the success of the individual as a result of their participation in the hunt, the favored strategy would simply be to hunt alone. In chimpanzees, individuals appear able to track the participation of group members during the hunt, resulting in preferential access to the meat by those who actively participated in the hunt (Boesch 1994).

It is only in societies where participating in the common task yields a net benefit that exceeds that of participating in a comparable task alone that cooperation should evolve (Boesch 2002). For example, if all individuals participate in the hunt, yet only one individual reaps the rewards of that hunt, this pattern of behaviors would not be evolutionarily stable. The observance of cooperative hunting animal societies has lent to an understanding of the conditions under which a hunting strategy is uniquely viable. Animals, such as wolves, whose main source of prey are large ungulates, which are difficult to take down individually, would benefit greatly from working as a group (Muro et al. 2011). Often, these animals face the challenge of hunting in open landscapes, necessitating more creative tactics (i.e., distractions, harassment, etc.) to effectively hunt (Bednarz 1988). In addition to open habitats, hunting in three-dimensional habitats, such as forests, also benefit from group coordination (Stander 1992).

By definition, cooperative hunts require a minimum of two individuals, and there are a number of conditions that dictate the optimal sized group. There appear to be two peaks in amount of food intake as a function of group size: the first is when there is only one individual and the second is when there is a particularly large group (Boesch 2002). When the prey item is relatively easy to

catch, smaller group sizes are more favored. When the prey item is larger and more difficult to take down, greater numbers are far more common (Stander 1992). Interestingly, as the group grows larger, there is often a higher prevalence of cheating, diminishing the advantages of cooperation for those participating (Stander 1992).

Even if a larger group size lends itself to increased cheating behavior, there is the added benefit of post-hunt protection. Lions (*Panthera leo*) may lose up to 20% of their prey to scavenging hyenas, with this value increasing as the number of lions present around the carcass decreases (Boesch 1994). This is a similar pattern to that seen in African painted dogs (*Lycaon pictus*); a group of two or three individuals have a greater likelihood of losing their kill to hyenas. An increased number of dogs would allow for a more successful counterattack against the scavenging hyenas, thus maximizing the amount of meat the dogs are able to consume following a successful hunt (Estes and Goddard 1967).

Most cooperative hunts are variants of the coordinated stalking of prey (Stander 1992). Wolves (*Canis lupus*) often rely on ambush hunts, wherein one individual lays in wait as the other members of the hunting party drive the prey toward the ambusher, as well as relay running, which is characterized by hunters rotating their roles and position with the pack during a chase (Muro et al. 2011). The division of labor – wherein members perform different, but complementary roles during a hunt – is a hallmark of cooperative hunting (Gazda et al. 2005). Role specialization within the division of labor is the tendency for individuals to consistently perform certain tasks during hunts, rather than changing the roles they perform within and between hunts (Gazda et al. 2005).

Observations of Tai chimpanzees have revealed three broad categories that individuals fall into during hunts: hunter, cheater, and bystander. A hunter directly participates in the hunt, contributing in some way to the capture of the prey. While this strategy requires the highest energy input, it is the strategy that yields the best access to meat following the hunt (Boesch 1994). Cheaters, in contrast do not participate in the hunt,

but are present following the hunt to eat the meat. They exert the least amount of effort but are also punished for their nonparticipation. The cheaters who are closely related to hunters tend to be tolerated more than distantly related individuals in the same capacity (Boesch 1994). The role of bystander is often more fluid, with those individuals moving in and out of that role into either hunter or cheater roles (Boesch 1994).

Mutualism is described as individuals accruing benefits from working together that surpass those they would have received when working alone (Boesch 2002). This explains the increased access to meat enjoyed by hunters. Reciprocity, on the other hand, is how females are able to get preferential access to meat in societies where hunting is performed by the males. Under the principles of reciprocity, the benefit to each individual is experienced at different times, and it is through repeated interactions that this relationship develops (Boesch 2002). Females are able to leverage mating access in exchange for meat following a hunt (Boesch 1994).

## Chimpanzees

Tai chimpanzees are well-known for their cooperative hunting practices, collaborating in nearly 70% of their hunts (Boesch 1994, 2002). Not only do they perfectly emulate the necessary conditions for cooperative hunting to be evolutionarily stable in their society, they are also a species that exhibits role specialization (Boesch 2002). Drivers are tasked with progressing the hunt in a certain direction, moving toward the prey, but never trying to catch up. Chasers are similar to drivers; however, they intentionally attempt to catch up to the prey. Blockers strategically place themselves at points through the forest, forcing the prey to maintain their progression in a specific direction. Finally, the ambushers position themselves in a tree where they anticipate the hunt will lead to attacking the prey once it enters that tree (Boesch 2002). Ambushers and blockers require a level of forethought in anticipating where the prey will be and at what time in the hunt. This complex

ability requires extensive training and practice; it can take up to 20 years for individuals to become consistently proficient at anticipating the behaviors of (Boesch 2002). Blockers and ambushers are more valuable than drivers and chasers to the success of the hunt, allowing them increased access to meat above and beyond that of hunters in lesser positions. The particular role adopted during the hunt supersedes any dominance hierarchies (Boesch 2002).

## African Painted Dogs

African painted dogs have an incredibly high success rate when hunting as a pack. With a hunt lasting an average of 25 min and a success rate of over 85%, they are an ideal example of cooperative hunting (Estes and Goddard 1967). There is not a clear division of labor during the hunt, as they tend to rely on a relay-running strategy when hunting, and there is always a leader who leads the pack during the chase (Estes and Goddard 1967). Resource sharing among African painted dog packs is less dependent on participation in the hunt, as is the case with other species. This is not to say that cheating is permitted within the pack, but rather that resources are shared with family members who could not be present during the hunt, such as mothers with new pups and sick individuals (Estes and Goddard 1967).

## Lions

Lions demonstrate the increased efficacy of role specialization during hunting. They commonly exhibit a hunting configuration wherein some lionesses, known as “wings,” encircle their prey, while others, known as “centers,” slowly stalk toward the group, ambushing prey fleeing from the “wing” lionesses (Stander 1992). Despite moving shorter distances than their counterparts, kills made by “centers” accounted for 73% of their successful hunts. This stalking-ambush strategy was most effective when lions were in their preferred roles during the hunt (Stander 1992).

## Harris Hawks

Cooperative hunting is not limited to mammals. Harris hawks (*Parabuteo unicinctus*) have demonstrated increased success with larger hunting parties (Bednarz 1988). These hawks follow a pattern of behavior when searching for prey in which they will “leap-frog” throughout their home range, splitting into subgroups and flying from perch to perch. After locating a prey item, they will employ one of a number of common hunting tactics. The most common is known as the “surprise pounce” wherein individuals converge on the prey from different directions (Bednarz 1988). Another tactic is known as the “flush and ambush” strategy and is employed when their prey is able to find temporary cover. In this series of behaviors, a number of hawks will attempt to penetrate the cover while other individuals wait, watching for the prey to reappear (Bednarz 1988). The least common tactic is the “relay attack,” which is a long-duration chase intended to exhaust their quarry, wherein some pursuing individuals will pause at a perch, allowing other group members to fly ahead, continuing the chase (Bednarz 1988).

## Conclusion

Cooperative hunting relies on two underlying conditions to be an evolutionarily stable strategy: the probability of a successful hunt must be higher when in a group than when alone, and there must be some deterrence against cheating behaviors. There are three roles into which individuals may fall during a hunt, and those are hunter, cheater, and bystander. Some species, such as the African painted dog, are more tolerant to those who do not participate in the hunt, while other species, such as chimpanzees, are far more intolerant of cheaters. This is not a steadfast rule, however, as female chimpanzees are able to leverage future benefits to the hunters in exchange for meat. There are numerous tactics employed by different species; however, the common thread among these strategies is a division of labor. Some species may have

a more rudimentary version of labor division, whereas the hunting success of other species is more directly tied to role specialization of the individuals. Harris hawks, for example, readily switch roles to suit the present circumstances; in contrast, lions have far higher success rates when group members are serving in their preferred position. The behaviors and conditions associated with cooperative hunting lay on a spectrum of complexity.

The problem of social coordination is widespread across species and contexts, ranging from group cohesion and movement to courtship, aggression, and cooperation (see chapters on “► [Pro-social Behavior](#),” and cooperation for

more information on these topics). The primary similarity across these topics, uniting them under the umbrella term “coordination,” is that the outcome is due to joint action by two or more individuals at the same time that results in a desired outcome. Coordination is often used more or less interchangeably with cooperation in biology; however in economics, coordination specifically focuses on how individuals synchronize their behavior to reach (or not) a common goal (Guastello and Guastello 1998). It is often studied using coordination games, in which subjects benefit by coordinating their responses on the same outcome. These games are part of a set of tasks used in experimental economics to explore decision-making outcomes in humans. Aside from being useful to better understand human decision-making, the games are particularly amenable to comparative research (Smith et al. 2018) and thus can provide important insight into the evolution of decision-making, including coordination (Brosnan et al. 2013). We focus on two games, a coordination game called the Assurance game (or Stag Hunt game) and the closely related Hawk-Dove game (or Chicken game), an anti-coordination game.

Economic games take complex decision situations, such as coordination, and break them down to very simple choices. These choices are often dichotomous, although they can be more complex. The experimenter can also manipulate the paradigm to explore how decisions change in different contexts or within different social environments or alter the payoffs to explore how different types of decisions compare (i.e., coordination vs. anti-coordination). Due to their simplicity, these games can be easily adapted for multiple species and for use with different types of tasks, for example, either a manual task (e.g. choosing which of multiple tokens to return) or a touch screen or joystick-based computer task (e.g. choosing by selecting one of multiple icons on a screen). This is a key advantage for comparative work, since even basic morphological differences between species can strongly impact the degree to which the same task can be used with them, making these games particularly well suited for studying the evolutionary trajectory of decision-

making. Although the games themselves are artificial, they are an excellent model system that can be used to derive hypotheses that can then be tested in more species-specific paradigms (Smith et al. 2018).

A key difference, of course, is that we cannot explain to nonhumans how the games work. This is typically solved in one of two ways; either they are allowed to learn the payoffs as they learn the task, or they are trained on the payoffs and then researchers explore whether their decisions change across different contexts. The former can be particularly useful in learning how subjects figure out what “game” they are playing, what the payoffs are, and how their decisions change as they learn the parameters. This is also relevant for understanding how people interact in non-laboratory situations. Although in the laboratory we can tell people the exact parameters of a decision task, in real life, individuals must figure out both the structure of the interaction and what the payoffs will be, the latter of which are often not foreseeable at the outset. Of course, this also means that we cannot be certain that subjects understand the task as we intended. As a result, it is important to “back-test” the adapted games that we use with animals on humans, using the same procedures that the other species received. Aside from ensuring that the humans respond to the modified game as expected, which indicates that the changes did not impact the goal of the procedure, it also verifies that any differences between humans and other species are due to differences in how they perceive or engage with the game, rather than differences in the procedure, and that similarities are really due to similarities in response, and not a result of having inadvertently made the game easier for one of the species.

### Assurance Game (Stag-Hunt)

The Assurance game (also referred to as the Stag-Hunt game) is an example of a simple coordination game with two pure strategy Nash equilibria (NE; strategies whereby no player can do better by changing their strategy if their partner’s

play remains consistent). The game was originally presented as a story by Jean-Jacques Rousseau and later modeled to a social dilemma (Skyrms 2003). In the story, two hunters can work together to take down a stag (a large prize), or they can individually hunt a hare (a much smaller prize). The dilemma is that while both individuals benefit more from working together to get the stag, if their partner does not participate, those that try for the stag outcome end up with nothing. However, they are always able to hunt the hare on their own. Thus, the dilemma is that participants both benefit the most from working together, but if they do not trust their partner, or think that their partner may not understand the task, they should make the lower-paying, but safe, choice to hunt hare.

This game is little studied in humans, likely because if the game is explained as we have just done, or a payoff matrix is presented, it is obvious that there is a mutually beneficial, high-paying outcome, which is what people overwhelmingly play. Therefore, most research studying cooperative decision-making in humans has focused on the Prisoner’s Dilemma, a cooperation game in which there is a high temptation to defect (for a better payoff), unless individuals play with the same partner repeatedly, in which case the gains from long-term cooperation outweigh the (one-time) gain from defecting on a cooperating partner, that will likely be followed by mutual defection. However, even in an Assurance game, if you do not know the payoffs ahead of time, and must learn them as you play the game, coordination may be harder to find than the human results imply. As mentioned above, this is true not only in the tasks used with nonhuman species, but often in real life. Indeed, Brian Skyrms, in his influential book on the Assurance game, has argued that it is a better model of many instances of human decision-making and deserves more attention (Skyrms 2003).

A growing body of literature has explored the Assurance game in nonhuman species. An initial set of studies, derived directly from the experimental economics literature, used two different methodologies, a manual exchange task common

**Coordination Games,**

**Fig. 1** Payoff matrices associated with the Assurance game (a) and the Hawk-Dove game (b)

|          |      | Player 1 |      |
|----------|------|----------|------|
|          |      | Stag     | Hare |
| Player 2 | Stag | 4, 4     | 0, 1 |
|          | Hare | 0, 1     | 1, 1 |

|          |      | Player 1 |      |
|----------|------|----------|------|
|          |      | Hawk     | Dove |
| Player 2 | Hawk | 0, 0     | 1, 4 |
|          | Dove | 4, 1     | 2, 2 |

in nonhuman primate studies and a computerized task that is the traditional methodology in human studies. In both cases, subjects made a choice among two options (either computer icons or tokens) and rewards were distributed according to the same payoff matrix (Fig. 1a: Brosnan et al. 2011, 2012). In the computerized task, there were two conditions, a functionally simultaneous condition, in which subjects could not see their partner's choices until both had made a choice, and a sequential version, in which subjects' choices were displayed immediately as they made them, so subjects could at least in principle use their partner's choice to guide their own decision.

Researchers have ultimately tested five species representing a wide phylogenetic range within the primate order. This included humans, as well as three other primates that are highly cooperative and social and do well on a variety of cognitive tasks; chimpanzees (*Pan troglodytes*), rhesus macaques (*Macaca mulatta*), and capuchin monkeys (*Sapajus [Cebus] apella*). Chimpanzees are often used as a comparison with humans as they, with their sister species bonobos, are the extant great apes most closely related to us. Bolivian squirrel monkeys (*Saimiri boliviensis*) were also tested, which are closely related to and live in similar habitats as capuchin monkeys (both New World primate species) but do not show extensive cooperation. This allowed a determination of whether cooperation in daily life enhanced the ability to coordinate in this task.

The overall results showed clearly that some pairs of all of these species, including squirrel monkeys, coordinate on the payoff-dominant NE (*Stag-Stag*) in some contexts. However, there was substantial variation in how they did so (Brosnan et al. 2011, 2012; Vale et al. 2019). The New

World monkeys, the most distantly related to humans, did the least well on the task. Three out of the five pairs of squirrel monkeys tested settled on the payoff-dominant NE, but while these pairs' results were statistically significant, anecdotally, their frequency of choosing the *Stag-Stag* outcome was lower than that of the other species who found the NE, possibly due to the fact that squirrel monkeys do not appear to cooperate in the wild to the same extent as the other species tested (Vale et al. 2019). Capuchin monkeys also showed low levels of success in a manual task, but all subjects found the payoff-dominant outcome in the sequential computer task. Rhesus monkey and chimpanzee pairs were able to coordinate on the payoff-dominant NE in both the simultaneous and sequential versions, as were humans, although chimpanzees were highly variable.

These studies also provided insight into the mechanisms subjects used to solve the task. Capuchin monkeys were only able to solve the task when they could see their partner's choices and were presumably using a matching strategy, with a bias towards the option that payed them better. Capuchins live in small, fairly cohesive social groups, and thus coordination likely occurs primarily when subjects are in close enough proximity to one another to see each other's choices (Fragaszy et al. 2004). Capuchins therefore may have never experienced selective pressure for a mechanism for coordination other than behavioral matching or monitoring. Rhesus monkeys and chimpanzees (as well as humans) live in much larger social groups that frequently find individuals at much greater distances, or out of view. For example, chimpanzees coordinate behavior during group hunts and territorial patrols when

they are out of view of one another (Boesch and Boesch 1989; Mitani and Watts 2005). This presumably provided selective pressure for the ability to remember partners' past patterns of behavior even when they are out of sight.

Additional studies demonstrated that even the consistently successful rhesus monkeys were using a mechanism that was different than the humans'. In a control task in which subjects played a computerized simulation that was programmed to play different rates of *Stag*, humans probability matched, playing *Stag* at roughly the same levels as the simulation. Rhesus, on the other hand, played *Stag* almost no matter what the simulation played, indicating that they had simply formed a preference for this (typically) high-paying option (Parrish et al. 2014). This is particularly interesting as rhesus monkeys are known to probability match in other contexts, reinforcing that just because a species can use a particular cognitive mechanism does not mean that they will do so in every case; mechanism cannot be assumed from outcome. Finally, chimpanzees showed a high degree of variability, with chimpanzees that had extensive experience with cognitive tasks showing evidence of maximizing strategies that they could apply to novel situations. Chimpanzees who had very little experience with cognitive tasks, however, tended to match their partner, but with no bias towards mutual *Stag* play, or show no strategy at all (Hall et al. 2019). Although matching was still a relatively high-paying option, they would have done much better by coordinating on *Stag*. These chimpanzee results are hard to explain, given their behavior in the wild, and suggest the possibility that they were either failing to understand the task or were not motivated by it.

Humans showed one other curious outcome; in the manual task, many of the pairs settled on the risk-dominant *Hare-Hare* outcome. Looking at the data more deeply, however, it turns out that these pairs did not explore the parameter space and had never experienced the payoff-dominant *Stag-Stag*. It appears that after finding the *Hare-Hare* outcome, these subjects thought that they had solved the task and did not explore further. Language may be particularly

relevant for humans in this context; in neither task were subjects explicitly told not to speak, but only in the computerized task did all pairs do so. Intriguingly, pairs that spoke about the game found the coordinated *Stag* NE, whereas pairs that never talked about the game settled on the mutual *Hare* outcome and, again, did not explore beyond this. These results may indicate that humans are using language to facilitate exploration of the parameter space.

As mentioned above, while the economic games are valuable for cross species comparisons, additional information can be gleaned from using tasks that take into account more species typical behaviors. In another series of studies, chimpanzees and children were presented with a paradigm that closely mimics the original Stag-Hunt story on which the Assurance game is based (Bullinger et al. 2011; Duguid et al. 2014). Pairs could individually forage on a low-value food (*Hare*) or move to a high-value food (*Stag*) that was only obtainable if they coordinated with their partner. Once they left the *Hare* option though, they were not able to return to it if their partner did not show up for coordination on the *Stag* option and were thus unable to acquire any additional rewards.

As in the economic games, both chimpanzees and human children were able to successfully coordinate on the mutually beneficial *Stag-Stag* option at very high rates. Both species primarily relied on a "leader follower" dynamic, where one subject would make their decision based on what the other did. Interestingly, when the experimental setup was changed so that subjects were not as easily able to see their partner's decision (similar to the simultaneous version described earlier), rates of coordination decreased for the chimpanzees but remained high for the children. The researchers evaluated rates of communication between the species and found that children were able to maintain higher rates of successful coordination than chimpanzees in this more difficult scenario by increasing their verbal communication to replace their prior visual monitoring. Together with the humans' outcomes in the Assurance Game prior game task, these results emphasize the importance of communication for humans in coordinating outcomes.

## Hawk-Dove (Chicken) Game and Snowdrift Game

Sometimes individuals may be forced to confront a scenario where *anti*-coordination is required. This dynamic is captured best by the “chicken” game (made famous in the final car scene in the movie *Grease*). If two individuals are approaching one another head on, both individuals do best if one of them yields (to avoid injury), but the optimal choice for each is to maintain their course while the *other* yields (so they gain status). The optimal decision thus depends on doing the opposite of what the other individual is doing. This game has been studied extensively in behavioral ecology as the Hawk-Dove game, which models resource conflict but reflects the same payoffs as the chicken game. Whereas in a coordination game the Nash equilibria are for both players to coordinate on the same strategy, in an anti-coordination game the NE is for players to play different strategies. The Hawk-Dove game has three NE, two pure strategy, asymmetric NE where each player plays one of the options (the other plays the opposite strategy; bottom left and top right quadrants in Fig. 1b), and a mixed equilibrium where the players switch between these two pure strategies. The mixed equilibrium is the best equally paying solution because it maximizes both players’ benefits.

In a manual version of the Hawk-Dove game, using the token-exchange paradigm described above for the Assurance game, humans, but not capuchin monkeys or squirrel monkeys, were able to settle upon stable NE solutions (Brosnan et al. 2017; Vale et al. 2019). However, in a computerized version of the Hawk-Dove game (again using the same experimental methodology as described for the Assurance game), capuchin monkeys and rhesus monkeys settled on an asymmetric NE, although they were only consistently able to do so during the sequential version, in which they could see their partner’s choices (Brosnan et al. 2017). The difference in capuchins’ play between the two methodologies is likely due to the fact that aspects of the computerized task may enhance learning; because computers are faster than humans, the reward more rapidly follows the

choice, there are more trials per session, and despite all of the controls in place during the manual tasks, there are presumably fewer distractions in computerized testing. Humans performed notably better than the other primates, with nearly half the pairs finding the mixed equilibrium, in which the players alternated between the two asymmetric NE. Indeed, this result is notable because unlike the other primates, who maintain the same level of finding the NE or do so in fewer circumstances in the Hawk-Dove game, the humans do much better in this more difficult game. One hypothesis is that, unlike in the Assurance game, where the coordinated *Hare* outcome may have seemed like a good solution in the absence of full information, the variability in this task may have meant that humans did not think that they had found a solution and were therefore more likely to explore.

A closely related game is the Snowdrift game (see chapter Snowdrift Game), modeled after a scenario in which two cars are prevented from getting home by a large snowdrift. The drivers both want the snow to be shoveled and could work together to do so, but both drivers would prefer that the other driver does it on their own. If the other driver does not do the work, however, the first driver should shovel the snow because the cost is less than the benefit of getting home (but does allow the partner to free ride). To test this, chimpanzees were presented with a situation in which they could work together to pull in food rewards or wait for their partner to pull them in (they received the same amount of food whether or not they helped). If neither individual pulled, the rewards were lost to both. Chimpanzees generally coordinated, pulling together with the partner, although they did seem to strategically minimize their effort by waiting longer to pull when the effort required for pulling was greater (Sánchez-Amaro et al. 2016).

## Conclusion

Economic games are extremely useful for both determining how outcomes are similar, or not,

across species and the underlying mechanisms behind them. Future research should focus on expanding the species tested, in particular testing species that are not known to coordinate extensively in natural contexts, to determine the degree to which individuals can find coordinated outcomes even if they have not been in environments that selected for it, or whether such an evolutionary history is critical for developing coordination. In addition, as we discussed above, the economic games are an excellent model that allows for direct comparisons across species, but they lack ecological validity. It will be important to continue to test the hypotheses that emerge from these games using more species-specific designs that allow us to explore how ecological pressures may have influenced species differently.

There are also other factors that may be influencing behavior in these games, such as hormones, social partner identity, or previous experience with cognitive testing. This will be particularly important to understand how these factors influence behavior across species. For instance, while previous research has demonstrated impacts of oxytocin on behavior in economic games in humans (Dreu et al. 2010; Rilling et al. 2012), recent work in capuchin monkeys finds no such effect (Smith et al. 2019). Social partner may also play a key role, as individuals should coordinate differently depending on their relationships, and as our chimpanzee results demonstrate, previous experience with cognitive and behavioral testing may be critical. Finally, we need data from a wider range of coordination games. The Battle of the Sexes game would be particularly relevant, as it is a coordination game with conflict (as opposed to an anti-coordination game like the Hawk-Dove game), where individuals do best to coordinate together on one outcome or the other, but there is disparity between the player's individual preferences for each outcome. The addition of a wider range of species and modeled scenarios such as this would improve our understanding of the evolution of coordinated behavior and social decision-making in general.

## Coping Mechanism

### ► Coping Style

## Coping Style

Rachel Baumgardner

Michigan State University, Lansing, MI, USA

## Synonyms

Behavioral profile; Behavioral syndrome; Consistent behavioral variation; Coping mechanism; Stress coping; Temperament

## Definition

A specific response pattern involving behavioral, physiological, and endocrine-immune responses in an individual animal to stressful stimuli that is consistent across time and various situations.

## Introduction

Coping styles have been widely defined in humans, from responses to disease to response to emotional stressors. Much that we know in both humans and animals is derived from Henry and Stephens in 1977. In animal research, specific coping styles were not explored until 1990 (de Boer et al. 1990), when stress hormone responses in rats shocked by electrical prod were measured. This research discerned two “types” of rats, and used the same vocabulary as in human psychology: passive rats (those that froze in response to being shocked) and active rats (those that attempted to bury the prod in bedding). These terms were later altered to reactive and proactive.

Continuing research has been conducted on a variety of species; primarily lab animals, but also poultry, swine, cattle, aquatics, wild deer, etc. Coping styles have been associated with vulnerability to stress-related diseases, evolutionary fitness, and thus, population ecology, production indexes, fear-related behavior, and aggression. Animal coping style is a qualitative measure of stress response, whereas a behavioral axis is a quantitative measure, i.e., the extreme nature or

amount of the response (Koolhaas et al. 2007; Steimer and Discoll 2005; Van Reenen et al. 2005).

## History

Before Henry and Stephens' research (1977), animals were thought to have two basal responses: fight or flight. Cannon in 1915 described the fight-flight response, where the animal has a "decision" to make when presented with stressful stimuli, either stand, analyze, and "fight" the stressor or turn and flee. Territorial control and aggressive behaviors were explained by this scheme in many different animals. It was not until Engel and Scmale (1972) when the second response type was described. They characterized it as the conservation-withdrawal response, which is controlled by cortisol release; the animal may become quiet or depressed in response to a stressor it cannot mitigate or retaliate against.

Von Holst et al. (1983) described responses in male shrews. Males, when placed in a novel environment with a resident territorial male, were characterized by their response to the threatening behavior. They described two distinct groups: an avoidant group and a freeze group. Later studies in mice reversed this study design and demonstrated two categories of readiness to attack an intruder. For example, Van Van Oortmerssen and Busser (1988) used genetics to breed high-readiness and low-readiness mice. Then, when these mice were placed within the same cage, the high-readiness mice consistently spent most of their time fleeing while low-readiness mice consistently remained immobile (Benus et al. 1991).

The hypothesis arose that the individual level of aggressive behaviors would relate to the individual's responses to environmental changes in general. Experiments testing this hypothesis in feral mice and rats demonstrated this individual tendency to follow consistent patterns in behavior in response to various environmental stimuli (De Boer & Koolhaas 2003; De Boer et al. 2003).

Behavioral correlation can be explained by Tinbergen's classifications of behavior (1972). The proximal explanation could involve

pleiotropy, where similar genes have a causal connection between traits, or similar hormones act on the same target receptors (Ketterson and Nolan 1999). Developmental explanations involve environmental conditions shaping behaviors in microenvironments on the individual basis (Stamps 2003). Functionally, certain coping styles can be selected for – or, in a historical explanation, they may be inherited from an ancestor.

It is generally accepted that coping styles are a component of the animal's overall psychology and behavior, and, when combined with behavioral axes, temperaments, and aversive responses, can perhaps be called animal personality. The idea of animal personality has become increasingly popular in animal behavior and neurobiology research; however, the general unease of anthropomorphizing has caused some reluctance to the term (see Vonk et al. 2017).

## Assessment and Utilization

There are many well-tested methods for assessing coping styles in animals. Many studies utilize neuroendocrine response levels in hormones like norepinephrine and epinephrine, and stress hormones like cortisol and corticosterone. This allows researchers to determine whether the animal is physiologically reacting in a more sympathetic or parasympathetic manner. Higher sympathetic levels should correlate with higher levels of aggressiveness, higher heart rate, and lower hypothalamus-pituitary-adrenocortical (HPA) axis reactivity, i.e., lower glucocorticoid production. The correlation between stress response and coping style determination has been challenged and a more popular hypothesis suggests a multidimensionality to individual variation.

Various behavioral tests are used depending on species. These tests strive to both assess personality components like exploration, impulsivity, and docility and the physiologic components, like heart rate, breathing rate, and cortisol levels. Tests assessing coping styles often have a restraint component or a novel component, whether it is a novel object, stimulus, or environment. Neophobia, or fear of novelty, is frequently assessed.

In piglets, one of the methods coined the “back test” involves putting a piglet on its back and restraining it for a certain amount of time (Bunter and Lansdowne 2004). Vocalizations and number of attempts to escape are recorded. Arena tests are used primarily in ruminants; the animal is placed in a novel enclosure with a human stranger. This test measures docility. The animal is measured based on how many steps it takes, how fast it moves, how far it stays away from the human, and how many vocalizations it produces. Similarly, open field tests place the animal alone in a novel area, where it cannot see other members of its flock or herd (Koolhaas et al. 2007). This test is done typically in poultry or herd animals. It assesses response to isolation and unfamiliar surroundings and exploration; vocalizations and number of steps are recorded. In larger ruminants, like cattle, flight speed is a marker of fear response after being processed and handled in a squeeze chute (Koolhaas et al. 2007). In aquatic species, fear response is measured by aversion tests with avoidance learning (Martins et al. 2011; Ferrari et al. 2013). The fish is given a chance to escape aversive stimuli and latency to eat and recovery of cortisol levels are recorded.

Homeostatic control of serotonergic neurons as well as neuropeptides like vasopressin and oxytocin have also been utilized to assess coping styles (Koolhaas et al. 1999, 2007). Vasopressin is released in higher amounts in animals that are more aggressive than animals that show little aggression. Still, there is little known about the causation of different behavioral and neuroendocrine characteristics. We cannot, of course, assess one aspect of behavior without considering the rest of the animal. The neurobiology is important to consider in research going forward to develop models in understanding coping style. Once better understood, it is possible that coping style may be used to understand disease vulnerability, population ecology, and animal welfare management.

Studies in behavior ecology have developed a model that determines how natural selection favors optimal coping styles in certain environmental contexts. Coping style as a conglomeration of territoriality, nesting behavior, foraging behavior, mating, antipredator defenses, etc., in

the wild may create an advantage for some animals and a disadvantage for others, thus affecting overall fitness. For example, aggression may be favored in an environment where territory and social hierarchy are important, but may be an inappropriate expense of energy and resources in another environment. Coping styles may provide an explanation as to why some apparently maladaptive behaviors persist throughout an environment or a species, depending on the cost of the maladaptive behavior versus other benefits, demonstrated in sunfish that chose to remain in fish pools during the day to feed, even when predation was at risk (Sih et al. 2003).

## Current Classifications

A summary table is provided below (Summary Table). The classification of coping styles is bimodal in nonhuman animals. Koolhaas et al. (1999) defined them as proactive and reactive; Wilson et al. (1994) used the terms boldness and shyness in marine animals. The proactive or “bold” animals are characterized by less fearfulness in arena tests, fast exploration in open field tests, higher aggression, and higher sympathetic responses. The reactive and “shy” animals explore the open field test more cautiously, are more likely to freeze in response to aversive stimuli, and have a relatively higher parasympathetic response to stress.

| Proactive (boldness)                  | Reactive (shyness)                 |
|---------------------------------------|------------------------------------|
| “Bold and aggressive”                 | “Cautious and shy”                 |
| Fast and superficial explorers        | Slow and thorough explorers        |
| Less fearful                          | More fearful                       |
| High sympathetic, low parasympathetic | Low sympathetic, high HPA activity |
| Lower immune response                 | Higher immune response             |

Cortisol measurements have been correlated with fear responses; thus, reactive animals usually have higher cortisol response as a result of their more reactive HPA axis.

Immune response has been recorded in relation to coping styles as well. Bolhuis et al. (2003) demonstrated that passive or reactive animals

mounted a higher immune response when infected. Thus, knowledge about coping styles could prove to be beneficial in production environments. Reactive classified piglets had increased weight gain post-weaning compared to proactive piglets (Giroux et al. 2000). In an intensive production environment, there may be selection pressure towards animals that fend off illness and have improved weight gain after stressful processing procedures. Proactive animals could be identified within a herd and managed differently to maximize their welfare and production potential.

## Conclusion

Coping styles in animals has intrigued behaviorists, ecologists, neurobiologists, and physiologists for many years. As more is discovered, it is becoming apparent that individual variation in animal personality is much more complex than we had assumed before. The two current classifications, reactive coping and passive coping, are continuing to evolve as we discover more about physiological and behavioral correlations. It is important that we continue to refine our knowledge of animal behavior and personality to fully understand animal cognition. Animal welfare, conservation, production, and medicine are all areas where understanding coping style will be beneficial.

Varanasi, UP, India

## Synonyms

CNVs; Copy number polymorphisms; Copy number variation analysis; Copy number variation detection; Copy number variations

## Definition

Copy number variant (CNVs) can be defined as an imbalance of genomic sequence (>50 bp) that alters the diploid status of a particular locus (Girirajan et al. 2011).

## Introduction

During the last few decades, followed by the human genome sequencing and resequencing process, it has been discovered that humans can not only differ at the level of DNA sequence but also in the number of copies of certain genes in genome. Such quantitative variation in genome, which include variation either in tandem arrays of repeats or insertions or deletions, are known as copy number variants (CNVs). Many a times CNVs lead to dosage imbalances. For instance, we carry two copies of a gene, one comes from paternal side and other one from maternal. Sometimes, only one copy may be present and on the other hand three or more than three copies may also be present. The basis for this alteration is mostly duplications and deletions, ranging in size from several hundreds to millions of base pairs.

Copy number variants play an important role in disease biology. The number of base pair differences due to CNVs between two individuals is almost more than threefold higher as compared with single nucleotide polymorphisms (SNPs). Considerable portion of human genome (approximately up to 12%; Redon et al. 2006) is considered to be CNVs. CNVs represent benign polymorphic variants present in >1% population and are well tolerated. This is also believed to play a significant role in human evolution. CNVs are a source of genetic diversity in humans often associated with genomic disorders.

CNV formation occurs by two recombination-based mechanisms, i.e., nonallelic homologous recombination (NAHR) and nonhomologous end joining (NHEJ) and retrotranspositions (Lee et al. 2007; Zhang et al. 2009). Recently a portion of CNV seems to occur as a consequence of

**Copy Number Variant (CNV), Fig. 1** Nonallelic homologous recombination (NAHR) and nonhomologous end joining (NHEJ) mechanisms for CNV formation have been shown, (1) shows NAHR which results in interchromosomal duplication and deletion, LCR is low

copy repeats, and (2) shows nonhomologous end joining in which if a double strand break is introduced, a dimeric protein Ku binds to DNA eliciting conformational changes, then sealing occurs by specialized DNA ligases (Lig IV)

fork stalling and template switching (FoSTeS) (Zhang et al. 2009; Perry et al. 2008) (Fig. 1). The mechanism of fork stalling and template switching can be summed up as under:

1. The replication fork stalls at a DNA lesion.
2. The lagging strand invades an adjacent active replication fork to a region with microhomology.
3. The lagging strand disengages once again and invades a further adjacent active replication fork where it anneals to another microhomologous region to restart synthesis.
4. Finally, the lagging strand returns to original replication fork to continue replication to the end of the chromosome.

A database named DECIPHER (Database of Chromosome Imbalance in Phenotype Using Ensembl) has been established by the Wellcome Trust Sanger Institute to enlist CNVs associated with genetic diseases. Other databases are also there, which include “Database of Genomic Variants” which was established by the Hospital for Sick Children, CNVD (Copy Number Variation in

Disease), and SCAN (SNP and CNV Annotation Database). Although majority of CNVs (~89%) are shared by diverse human races, their ancestry can be studied using CNVs, which have evolved to adapt different geographic environments.

## Mechanism of CNV Formation

The part of genome which is largely flanked by homologous repeats or segmental duplications is most likely to harbor CNVs. Tandem repetition of DNA segments lead to segmental duplications which are dispersed at different chromosomal loci through rearrangements. The CNVs which are associated with segmental duplications are mostly susceptible to chromosomal rearrangements via nonallelic homologous recombination. Some CNVs may be formed by nonhomology-based mutational mechanisms. There can be a relationship between the size of a CNV and the mutational mechanism associated with it. It has also been established that segmental duplications are generally associated with larger CNVs as compared to smaller CNVs.

## Role of Copy Number Variants in Evolution

An important aspect of CNVs which needs to be addressed is whether the pattern of CNVs is similar to other nonhuman primates or other organisms. In order to study the evolutionary significance of CNVs, chimpanzee and human CNV regions were compared. Analysis of copy number variations in human and chimpanzee genomes demonstrated greater role of CNVs as compared to SNPs. Majority of CNVs between human and chimpanzee genome is common, but one third of CNVs present in human genome is specific. Inbred strains of laboratory mice also harbor a large number of CNVs. CNVs may contribute to phenotypic variations in mouse strains. By correlating functional variations with CNVs identified in mouse it is possible to extrapolate the phenotypic consequences of orthologous CNVs in humans.

The role of CNVs in evolution can be studied by examining the persistence of different structural changes through multiple generations (Redon et al. 2006). Deletions generally experience negative pressure while presence of gene families indicates that duplications can experience positive selection.

## Analysis of Copy Number Variant

CNVs can be assayed using multiple methods, i.e., array CGH, SNP array or SNP chips with CNV markers, qPCR, next-generation sequencing platform, and high-resolution microarrays that include copy number probes and SNPs. BAC arrays were the first microarray platform used for detection of copy number variants which can detect deletions and insertions. Log ratio measurements are produced by this platform to identify deviations of patient's copy number state from normal. The log ratio values, which differ significantly from zero, represent the part of chromosome with aberrations. Copy number gains are indicated by positive log value ratios whereas loss in copy numbers is indicated by negative log value.

## CNVs and Genomic Disorders

Pathogenic role of CNVs came into picture with the elucidation of etiology of Charcot-Marie-Tooth Neuropathy type I (Lupski et al. 1991). It is well known that CNVs cover 12% of human genome and alter the gene expression; gene dosage CNVs are associated with many disorders, autism and schizophrenia being the most important in addition to sporadic and Mendelian diseases in humans. There are several neurological disorders associated with CNVs.

| Chromosomal loci | Deletion                 | Duplication       |
|------------------|--------------------------|-------------------|
| 16p11.2          | Autism                   | Schizophrenia     |
| 15q11.13         | Autism and epilepsy      | Angelman syndrome |
| 7q11.23          | Williams syndrome        |                   |
| 22q13            | Phelan-McDermid syndrome |                   |
| 22q11            | Schizophrenia            |                   |
| 17q12            | Autism and Schizophrenia |                   |

CNVs are also associated with several complex disorders, e.g., Lupus, Crohn, HIV-1. At least 20 nervous system-associated disorders which include Alzheimer's and Parkinson's disease have been reported to result from copy number variants. Gene associated with immune systems and brain development is more likely to be enriched by CNVs.

## CNV Map of Human Genome

A comprehensive atlas of CNVs in the human genome has been established. A first-generation CNV map of human genome was generated in 2006 by using SNP genotyping arrays for comparative hybridization intensities. The CNV map can be very useful in scanning for genes responsible for common diseases. CNV maps can be used to study familial genetic diseases and to target the disease-associated hot spot regions. This way a complete and accurate human genome reference sequence can be obtained.

## Conclusion

CNVs are major source of genetic diversity among humans and other organisms. CNVs also drive human genome evolution via exon shuffling and gene duplication. The pattern of CNV that each of us inherits is a reflection of our ancestry. However, frequency and occurrence of CNVs also vary in populations of different geographical locations due to selection pressure. Since CNVs often encompass gene they have an important role in diseases and drug response. CNVs, both inherited and de novo have been implicated not only in immunological and neurological disorders but also in kidney disorders, schizophrenia, autism, congenital heart disease, cardiomyopathies, etc. Genome sequencing and characterization of CNVs is required for assessing the pathogenicity of CNVs, which can be further utilized as an important tool in personalized medicine. Despite of numerous advances, many undiscovered CNVs may exist in human genome that need to be investigated for enhancing our knowledge about the formation, distribution, selection, and evolution of CNVs.

[Emulation](#); [Imitation](#); [Mimicking](#); [Object Movement Re-enactment](#)

## Introduction

Copying encompasses occurrences of social learning where observers reproduce the behavior, general behavioral organization, or actions of others. The broader term of social learning describes all instances of learning from others or their behavioral products (Heyes, 1994), so is not limited to copying; it includes simpler processes such as stimulus and local enhancement. Two main forms of copying, named imitation and emulation, are the focus of this entry.

Building upon previous classifications by Whiten and Ham (1992) and Whiten et al. (2009), we re-envision a copying taxonomy (Fig. 1), considering new developments in the field of animal social learning. Since these publications, the picture of copying has changed, and new theory and data thus warrant an update.

## Imitation

Colloquially, imitation often refers broadly to learning from others. The animal literature defines imitation more precisely, identifying subtly different forms. Whether animals imitate in ways homologous or analogous to humans is the subject of ongoing debate. Attempting to answer this question has been one of the main drivers behind dissecting copying into its many variants, as researchers traditionally attempt to rule out alternatives before concluding that behavioral similarity occurred through imitation.

## Bodily Imitation

Because imitation can enable high fidelity learning, some theorists postulate it plays an important role in the transmission of human cultures, permitting cumulative cultural evolution. In particular, “bodily imitation” is suggested to support complex cultural traits by enabling onlookers to precisely reproduce the actions they witness. For this reason, whether animals similarly match the *form* of others’ actions has received much research attention.

In one paradigm used by experimentalists, the “Do as I do” task, employed with animals ranging from primates, dogs, parrots to cetaceans, participants receive demonstrations of arbitrary and novel gestures (or sounds) before a trained request (like “Do this!”) is given. Researchers then assess whether observers faithfully reproduce the model’s bodily movements (“process copying”) without any contextual cues (end-state or location cues) that could contribute to behavioral matching. Typically, some behavioral concordance, such as in the domain of object-to-object acts, has been reported, although the proportion of actions animals reproduce is often low, and the acts that are mimicked can be imprecise (Huber et al., 2009). Such evidence suggests that some animals can, but may not readily, engage in bodily imitation. That animals enculturated by very close contact with humans seem to do better than their unenculturated counterparts in contexts such as these also has suggested that bodily imitation may not be intrinsic, but rather a learned ability facilitated by human engagement (Tennie et al., 2012).

Two-action tasks are also employed to assess copying (see Whiten et al., 2009). Groups are presented a puzzle box (sometimes called an “artificial fruit”) and demonstrations of either of two alternative means to open it. If different solutions then follow in each population, researchers conclude that individuals copied the solution demonstrated to their group. Many group level traditions have been demonstrated in diverse animal species using variants of this task, albeit the role forms of social learning other than bodily imitation may play in their formation is often not ruled out.

## Program-Level and Contextual Imitation

Two other categories of imitation, proposed by Richard Byrne, capture instances in which individuals socially learn hierarchical sequences of behaviors (“program-level imitation”) or copy the context in which to perform known behaviors (“contextual imitation”). These are distinguishable from bodily imitation as the faithful replication of behavioral form is not required. Although

the latter is named contextual imitation, such episodes are only loosely “imitative” as users are not learning others’ behavioral actions per se but “when” or “where” to perform a known act (see Bates & Byrne, 2010).

In contrast, program-level imitation, included in our copying classification (Fig. 1), requires something of the behavioral form to be replicated or learned, even if imprecisely. When tasks are difficult, and actions are complex, it is unlikely that observers, whether human or animal, will faithfully copy them all from the outset. In this situation program-level imitation comes into play, allowing onlookers to learn something of the overall structure of behaviors (Bates & Byrne, 2010). One illustrative example is gorilla nettle processing. Captive and wild populations show similarities in the elements they use for this multistage process but differences in their overall organization (Byrne et al., 2011). This suggests gorillas learn what the authors describe as the “gist” of the behavior from conspecifics, but not necessarily the minute actions involved (Byrne et al., 2011). One can imagine that a variety of

multistep actions, placing high demands on working memory, are learned this way, requiring repeated observations and individual practice to acquire, even in humans (e.g., learning complex dances or exercise routines).

Production Imitation

On the other end of the continuum to contextual imitation is production imitation (Bates & Byrne, 2010). Behaviors to-be-copied can either be known (within one’s repertoire) or novel (new to the observer), with the latter referred to as “production imitation.” The mechanics behind learning novel and familiar actions may differ, and many researchers suggest that copying new behaviors presents a more cognitively demanding challenge than contextual imitation. The Do-as-I-do tasks described earlier offer a way to establish if animals copy unfamiliar behaviors or sounds. Similarly, novel two-action tasks are appropriate for establishing whether new solutions spread within populations.

**Copying, Fig. 1** Varieties of copying. Bubbles on the right provide brief definitions of the distinctions made and the dotted line indicates the category may be a subtype of emulation and/or imitation

## Vocal Imitation

Vocal imitation is a specialized form of social learning that enables listeners to match vocalizations with their own auditory experiences. Local “dialects,” where song structures are similar within communities but differ across communities, such as those of some whales and birds suggest vocal imitation. These local dialects can emerge by juveniles imitating sounds of older individuals. They can also evolve as new variants are introduced – an example of cultural evolution. Important to assessing vocal imitation is that *matching* occurs socially, and not because of genetic similarity. Without matching sounds or hierarchical patterns, song modified by external auditory input would be more parsimoniously described as acquired through vocal social learning.

## Automatic Imitation

Automatic copying describes the observation that witnessing other’s actions can elicit the same act in the onlooker, a response so “automatic” that it interferes with the ability to perform a different action. Evidence for this is documented in dogs, budgerigars, and children. Dogs, for example, take many more trials to learn a behavioral method different from that demonstrated by their owners (opening a door with their head when their owner uses their hand (paw) and vice versa) than dogs that were rewarded for using the same demonstrated action (matching the body part (head or paw) of their owner) (Range et al., 2011). The difference is between “Do-what-I am-doing” versus “Do-what-I-am-*not*-doing,” with longer learning periods in the latter indicating difficultly inhibiting witnessed actions. Thus, depending upon task demands and what others are doing, the automatic imitation bias can facilitate or impede one’s ability to meet these demands.

## Over-Imitation

The final form considered is over-imitation, which describes the tendency to copy all witnessed

actions, even those superfluous to the task at hand. One benefit of over-imitation is skill development without necessarily understanding why actions are performed, which can play a role in the development of cultural norms and conventions. Limited tests of animal over-imitation have been performed, but there is little indication of its occurrence beyond humans, even in our closest living primate relatives. Horner and Whiten (2005) provide an illustrative example, comparing human children and young chimpanzees. Both species, presented with either opaque or transparent puzzle boxes, witnessed demonstrations of both causally relevant and irrelevant actions to open them. Chimpanzees and children reproduced relevant and irrelevant actions when the box was opaque, but children alone reproduced the irrelevant actions in the transparent condition. This, and many more studies since, indicates that humans over-imitate even when actions seem clearly unnecessary to task success. Whether tasks designed to assess over-*imitation* in humans and animals show imitation, however, remains to be clarified. Like the two-action tasks described, other processes, such as stimulus enhancement or emulation, may lead to observed behavioral similarity. Emulative learning is the second copying category to which we now turn.

## Emulation

One take home message from the animal imitation literature is their copying is often imprecise. Many researchers suggest that animals, particularly primates, emulate rather than imitate. That is, they learn something from other’s actions but rarely copy the behaviors themselves. Following previous classifications (Whiten et al., 2009), we briefly expound three forms of emulative learning.

## End-State Emulation

End-state emulation accounts for the potentiality that organisms, including humans, recreate desirable outcomes of others’ actions but use their own means to get there. Although individual learning

occurs at the process level, the end-state is replicated, thus being considered a form of “copying” (Whiten et al., 2009). A handful of studies demonstrate such learning in humans and animals. One illustrative example from nonhuman primates, in which there is strong evidence for this form of copying, comes from the “floating peanut task.” To uncouple learning from actions as opposed from action results, Tennie et al. (2010) provided apes either full demonstrations of how to solve this task – a model spitting into a tube to raise a peanut to where it was accessible, or goal demonstrations – a model pouring water into the tube to raise and collect the nut. As apes had only the former “spit” method available to them, if copying actions (imitation) was beneficial, apes should perform best in the “full” demonstration condition. This was not what was found; apes performed similarly in both conditions, suggesting emulative learning. This and other studies paint a picture of our closest living relatives as emulators that do not regularly mimic actions but assimilate goals and end-products using their own methods.

### Object-Movement Re-enactment

In object-movement re-enactment (OMR), instead of copying bodily actions to move objects, it is the object movements that are copied. That is, even if an observer does not attend to details of body movements, they could still learn from the action consequences. One way to test OMR is using “ghost displays,” also used as a control for emulation more broadly. To remove the need for actions, therefore ruling out imitative learning, objects are “rigged” so they are automated. Ghost displays with chimpanzees and humans demonstrate emulative learning suggestive of OMR, for example, chimpanzees re-enact the side to which a sliding door moves in the absence of a demonstrator. However, observing a model’s behaviors confers added benefit when tasks are more difficult, and ghost displays also indicate affordance learning or end-state emulation could be at play (reviewed in Whiten et al., 2009).

### Affordance Learning

Emulation also comes in the form of learning object affordances from watching others interact with the objects. Through “affordance learning,” individuals learn something of the physical features of items being manipulated by others, which helps them to similarly utilize the objects in their environment. For example, the utility of a chair may be unrecognized until seeing someone sit down on one. Any subsequent act of sitting may look like imitation – there are only so many sitting movements humans make; however, similarity can arise by socially learning the chair’s properties (Whiten et al., 2009). Returning to the floating peanut task, if participants learn the properties of the tube (that it can hold water) and/or water (a peanuts float in water) from social demonstrations, we would conclude affordance learning was at play. We distinguish this form of emulation to highlight that we do not include it as constituting copying, unlike the forms described above.

### Conclusion

Copying provides animals with an extra-genetic inheritance system that enables fast and efficient transmission of potentially adaptive information and skills, avoiding some of the costs associated with personally exploring the environment. Copying also plays an important role in homogenizing group level behavior such that traditions or cultures arise. While we know that many species are capable of social learning, the degree to which the many *forms* of copying may be shared remains less well understood. Dissecting the forms is consequential for recognizing the similarities and dissimilarities between human and animal learning, with implications for identifying their phylogenetic histories.

## Core Area

Luca Börger

Department of Biosciences, Swansea University,  
Swansea, UK

## Definition

The core area is the more intensively used internal part of a home range. Consequently, in the case of a perfectly uniform use of space across the entire home range, there is no core area. Core areas are measured in units of area and time and are generally identified by a change in the relationship between the area used and the probability of use.

## Introduction

It is a common observation that most mobile animals repeatedly use the same area over time, instead of roaming over the entire available landscape, and this area used by an animal over a specific period of time is defined as the animal's home range (Fieberg and Börger 2012). The movements of animals within a home range are also typically not uniform (Samuel et al. 1985), with certain areas used more frequently; this area of more frequent (or intense, or concentrated) use is called the core area (Clutton-Brock et al. 1982; Powell 2000; Wilson et al. 2010; Vander Wal and Rodgers 2012), and the area of the home range external to the core area is called the home range “periphery.” Within the core area, there is hence a higher probability to encounter an individual

animal (Wilson et al. 2011), and core areas may be associated with specific habitats and ecological functions; for example, core areas in fishers (*Pekania pennanti*), small carnivorous mammals found in the boreal forest in North America, tend to be located in areas with a more heterogeneous and diverse forest structure and composition (Sauder and Rachlow 2015). The location, size, and structure of core areas hence provide information on the ecology of animal movements and can also inform wildlife management and conservation, for example, for the planning of protected areas or for assessing the impact of land use changes (e.g., planning of new roads).

### Core Areas and Home Ranges

The core area is an internal part of the home range of an animal, and thus the latter must be estimated and quantified first; consequently, all issues concerning sample size and sampling design, home range estimation methods, etc. equally apply for core area estimation (Fieberg and Börger 2012). A home range is an emergent space use pattern that results from animals restricting their movements within a certain area over a certain time period, while attempting to meet their needs for growth, survival, and reproduction (Börger et al. 2008). A home range is estimated from a regular sample of animal movements, collected over a defined time interval, typically using GPS or VHF tags attached to animals, using statistical methods such as kernel density estimation (Fieberg and Börger 2012). It is important to use such methods as they provide an estimate of the relative frequency distribution within the home range area of an animal's location over time – this is called the utilization distribution function (UD) and can be thought of as a measure of the probability to encounter an animal in a certain area. UD values range between 0% and 100% and the area enclosed by a line of constant UD value, called an isopleth line, provides measures of home range and core area size – typically, 95% or 90% isopleths are used to delineate the home range (Fieberg and Börger 2012). Thus, methods such as kernel density estimation provide

estimates of both area and probability of use, both of which are fundamentally needed to identify a core area. Unfortunately, many researchers often use a shortcut, by arbitrarily defining the core area as the 50% UD. However, home ranges, and hence also core areas, are dynamic patterns which can change by several orders of magnitude within and between individuals (Börger et al. 2006); hence using such a constant criterion for all individuals will likely lead to strongly biased results and conclusions and should be avoided (Wilson et al. 2010; Vander Wal and Rodgers 2012).

### Identifying the Core Area

The concept of a core area is fundamentally linked to the relationship between the probability of use and the size of the area used by animals within a home range. If an animal would move in a uniform way across all the home range, a linear constant relationship with a slope of 1 would be observed between the probability of use and the associated size of each home range isopleth. In other words, the increase in the size of the area covered by a 25% UD isopleth compared to a 50% UD isopleth would be equal to the increase in the associated UD value. In reality, it is a common observation that animals tend to spend a disproportionate amount of time in a relatively smaller area of the home range and move less often in the remaining areas (Clutton-Brock et al. 1982; Samuel et al. 1985; Powell 2000); hence the area of UD isopleths first increases less slowly than the associated UD isopleth value, thus with a slope smaller than 1, and increases faster, with a slope above 1, beyond a certain UD value (Vander Wal and Rodgers 2012). The inflection point of this area vs. probability of use relationship is taken as the UD value delimiting the core area. Graphical methods were firstly used to identify the core area UD value (Clutton-Brock et al. 1982; Powell 2000); Vander Wal and Rodgers (2012) presented a more rigorous and repeatable approach, based on standard linear and nonlinear statistical models applied to the UD vs. area data. A major further improvement has been achieved by Wilson et al.

(2010), using a Bayesian-based approach which allows to more robustly identify the core area boundaries and, for the first time, also associated measures of uncertainty, as well as assess if the movement data support the case of a single- or a multi-core area. Using this individual-based, robust, and repeatable approach will allow to markedly advance the study of animal core areas to understand the underlying behavioral and ecological processes.

### Beyond the Core Area vs. Periphery Dichotomy

While the core area is an important and useful concept, the internal structure of home ranges can provide more information than simple core vs. periphery dichotomies; for example, Börger et al. (2006) showed that using multiple UD isopleth measures, closely linked to clear ecological questions, can markedly increase the biological inferences obtained. If sufficiently frequently sampled movement data are available, further understanding can then be obtained by using newer methods which go beyond the UD and directly allow to identify home range areas that are intensively exploited or repeatedly visited, as well as using multi-sensor biologging methods which allow to include further metrics, such as the type of behavior displayed at specific locations or the state of individuals.

### Conclusion

The core area is the internal, more intensively used, area of animal home ranges. It is a useful metric for understanding the patterns and drivers of animal movements and space use, but it is imperative that modern, repeatable methods are used, avoiding traditionally used arbitrary approaches. Further advancement will come from using methods which go beyond the core area vs. home range periphery dichotomy, integrating space use, movement, and behavior analyses.

## Correlation

Cash Kumar<sup>1</sup> and Akash Gautam<sup>2</sup>

<sup>1</sup>Department of Zoology, Banaras Hindu University, Varanasi, India

<sup>2</sup>Centre for Neural and Cognitive Sciences, School of Medical Sciences, University of Hyderabad, Hyderabad, Telangana, India

## Synonyms

Dependence; Statistical association

## Definition

Correlation, in statistics, is a predictive relationship between two variables. One can find out the nature, direction, and strength of the association between two factors by using this measure of dependence.

## Introduction

The word correlation is used in everyday life to denote some form of a relation between two random variables. We might say that we have noticed a relation between unemployment and inflation. Correlation is a real number that gives us an idea of the degree of association between two variables. At a basic level, it is also known as “bivariate” statistic. Thus, correlation is a unitless value that measures the strength of the linear association between two variables and the nature of the relationship. The relation between two factors can fluctuate from absolute to not at all.

If two variables are moving in the same direction, i.e., as one increases, another also increases, or as one decreases, another also decreases, then there will be a positive correlation between those variables. For example, the gravitational force increases as the mass of the object increases. However, if the changes in the two variables are in the opposite direction, i.e., if one variable increases the other decreases or vice versa, then there will be a

negative correlation; for example, the gas volume decreases as their pressure increases or the demand for commodity increases as the price of such commodity decreases. The absence of any relationship between the two variables leads to zero or no correlation (Kothari 2004); for example, the grades obtained by students in examinations and their height.

## Correlation Estimation

There are different ways of estimating the correlation between two random variables.

### Scatter Diagram

A scatter diagram is a diagrammatic method to observe correlation. Here, one variable, x-values are depicted on the horizontal axis and another variable; y-values are on the vertical axis. A pattern between the coordinates would indicate the correlation. If the trend is **downward sloping** from left to right, it means a negative correlation. If it is **upward sloping** from left to right, it means a positive correlation. If the points are scattered with no discernible linear pattern, then the variables are said to be **uncorrelated** (Fig. 1).

### Pearson's Correlation Coefficient

The correlation coefficient is another method of measuring the statistical relationship or strength of the association between the two variables. It is represented in an example by the value “r.” It can range from  $-1.00$  to  $+1.00$  (Fig. 2).

When the correlation coefficient approaches  $+1.00$ , it implies there is a **positive relationship (or perfect positive)** or a high level of association between both variables. It means that the greater or lower the score of a member on one variable, the greater or lower the score will be on the other variable, respectively. For instance, there is a positive correlation between height and weight of plants up to a particular age.

Though there are many measures of correlation, the **Pearson product-moment correlation coefficient**, which measures the degree of linear association between two continuous variables, is the most used measure (Gilbert 1986). Pearson's

**Correlation, Fig. 1** Scatter diagrams showing positive, negative, and no correlation between x and y variables

**Correlation, Fig. 2** The values of “ $r$ ” ranges from  $-1$  (absolute negative correlation) to  $+1$  (absolute positive correlation) including  $0$  (no correlation)

coefficient  $r$  is acquired for a sample drawn from a populace. The populace value of Pearson’s coefficient is called rho ( $\sigma$ ), and in this way,  $r$  is a gauge of  $\sigma$ . The formula for  $r$  is as follows:

$$r = \frac{N \sum xy - (\sum x)(\sum y)}{\sqrt{[N \sum x^2 - (\sum x)^2][N \sum y^2 - (\sum y)^2]}}$$

Note: In this formula,  $N$  is equal to the number of pairs of scores, and  $\sum xy$  is called the total of the cross products.

**Spearman’s Rank Correlation Coefficient**

Another measure to calculate the correlation coefficient is **Spearman’s rank correlation method**. It was formulated by an English psychologist Charles Spearman. This method uses a monotonic function to show the relation between two variables, unlike Pearson’s correlation, where it is for linear relationships only. Spearman’s correlation is a nonparametric measure and generally calculated for ordinal or ranked data (Kothari 2004).

Spearman’s correlation coefficient ( $r_s$ ) can be calculated by the following formula:

$$r_s = 6 \sum D^2 / N(N^2 - 1)$$

where

$D$  = difference between the observation of two ranked variables

$N$  = number of observations

The range of  $r_s$  is also  $+1$  to  $-1$ , similar to the Pearson’s coefficient.

**Kendall Rank Correlation Coefficient**

Kendall rank correlation method is an alternative to the Spearman’s correlation coefficient method, as the former one can be used to know the non-linear associations between the two variables. This simply means that it can measure the monotonic as well as linear correlation function. Kendall rank correlation coefficient ( $\tau$ ) is a nonparametric test and generally used for the small sample size or for

tied ranks. Kendall's correlation coefficient establishes the strength of association based on the pattern of concordance and discordance between the pairs of observations. For any given set of paired variables  $x$  and  $y$ ,  $\tau$  can be calculated as:

$$\tau = (\text{No. of concordant pairs} - \text{No. of discordant pairs}) / n(n-1)/2$$

where denominator  $n(n-1)/2$  represents the number of all possible bivariate data points.  $\tau$  also ranges from +1 to -1 for untied ranks.

### Mantel Test Coefficient

It was propagated by American biostatistician Nathan Mantel in the late 1960s. This test is used for non-normal distributions, mainly in the field of ecology and genetics, where data is presented in the form of two same dimensional matrices (Diniz-Filho et al. 2013).

Suppose there are two animal species  $i$  and  $j$ , with genetic distance ( $g_{ij}$ ) and geographical distance ( $d_{ij}$ ) between them, then Mantel test coefficient ( $Z_m$ ) can be given as:

$$Z_m = \sum_i \sum_j = 1/n \sum_i \sum_j g_{ij} \times d_{ij}$$

where  $n$  represents the total population.

Here,  $Z_m$  is just the summation of products of both distances. Therefore,  $Z_m$  will be contingent on the number of populations and the distances. In the late 1970s, the Mantel test met with several criticisms for biasedness as this test works fine only for large sample sizes. To avoid this partiality, a null distribution must be done empirically by permuting rows and columns of one of the distance matrices.  $Z_m$  ranges from +1 to -1.

### Phi Correlation Coefficient

The phi correlation method is again a nonparametric test that is used to show associations between two noncontinuous variables, for example, the number of males and females in a school. English mathematician Karl Pearson gave this method. Phi coefficient ( $\varphi$ ) can be calculated easily from the chi-square result as follows:

$$\varphi = \sqrt{(\text{chi-square} \div \text{sample size})}$$

However,  $\varphi$  is calculated only when  $p < 0.05$ ; otherwise  $\varphi^2$  (i.e., ratio of chi-square and sample size) is sufficient to measure the amount of variance in the dependent variable, which can be explained by the independent variable. For example,  $\varphi$  of 0.72 means that the independent variable accounts for 52% of the variance in the dependent variable. The  $\varphi$  ranges from 0 to +1, where +1 means there is a perfect 1 to 1 correlation between the two variables (Frey 2018).

### Significance of a Correlation Coefficient

It is essential to mention that just the value of  $r$  cannot convey any information about the good (significant) or weak (insignificant) correlation between the two variables because it also depends upon the number of observations under study. Therefore, in the absence of a sufficient number of observations, one cannot calculate the proper association between two variables.

### Conclusion

Correlation is one of the popular statistical tools to calculate the degree of relationship between two variables, and which is utilized by researchers in general. Depending upon the value of correlation coefficient ( $r$ ), one can categorize correlation as positive, negative, or no correlation. To obtain the correlation, one can proceed manually through the above formula or some readily available statistical analysis software like MS-office Excel, SPSS, etc. However, the main thing is to obtain the proper inference from the calculated  $r$  values in light of the number of samples and  $p$ -value.

## Corridor Illusion

Zachary T. Parsley and Stephanie A. Kazanas  
Department of Counseling and Psychology,  
Tennessee Technological University, Cookeville,  
TN, USA

## Synonyms

Ebbinghaus illusion; Ponzo illusion

## Definition

An illustration of size constancy in which two identical figures appear to be radically different in size. If the figures are placed in a picture of a corridor, the one placed in the distance appears larger than the one placed in the foreground. This is because depth cues affect expectations about true size (APA [n.d.](#))

## Introduction

In terms of visual perception, several species of animals share a common array of visual illusions. In particular, many animals are susceptible to the corridor illusion. This illusion occurs when objects of the same size appear to be different sizes due to positioning in a corridor. Humans are commonly studied for this illusion, but expansive research is currently being conducted to determine similar visual perceptions in animals. This will allow researchers to better understand the cognitive processes that animals have by comparing their visual processing to humans. Much research has focused on primates, given their high genetic similarity to humans.

Barbet and Fagot (2002) studied baboons (*papio papio*) to determine the extent these

primates experience corridor illusions. The experiment indicated chimpanzees do in fact experience corridor illusions, since the primates responded differently between stimuli (images of humans) in a corridor. More specifically, the baboons were trained to move a joystick when the images of humans appeared to be different sizes. Additional data collected by Imura, Tomonaga, and Yagi (2008) showed there are slight differences between humans and chimpanzees. Both chimpanzees and humans responded to the stimuli in a manner that signified that each perceived corridor illusions in the study, but chimpanzees were more inclined to report these illusions when the stimuli were placed closer to a ceiling; humans were more likely to notice the corridor illusion if the stimuli were closer to the floor. This was hypothesized to be caused by evolutionary differences, such as each species adapting to the environment that is inhabited.

Primates have been a major focus in research on this topic, but other studies have shown potential evidence that corridor illusions exist in species less related to humans. In one example, Hataji, Kuroshima, and Fujita (2020) tested the visual perception of pigeons, providing significant statistical support for corridor illusions being an aspect of pigeons' visual processing.

## Factors in Corridor Illusions

Contextual cues and perception are what influence visual perception causing corridor illusions, but other factors could also contribute. For example, linear perspective is a prime reason for differences in depth perception of visual stimuli, which changes the appearance of objects (Yildiz et al. 2019). Furthermore, the spatial layout of these experiments appears to enhance or reduce the corridor illusion. Spatial differences alter the perception of visual content, thus changing the perception of the observer (Richards and Miller 1971).

## Conclusion

Evidence for the perception of corridor illusions is accumulating across various species, including humans, chimpanzees, and pigeons. Importantly,

research has determined there are several factors that lead to and moderate corridor illusions. Contextual cues are often held as one of the most prominent reasons for the illusion. Other studies suggest linear perspective and evolutionary traits inhibit this visual process.

## Alternative Words

Corticosteroid; Steroid hormone

## Definition

Corticosterone is an adrenal steroid hormone, the major glucocorticoid released by the mammalian systems (except humans). Glucocorticoid hormones are also referred as corticosteroid hormones synthesized mainly in the adrenal cortex; however, more recently the enzymes involved in their synthesis have been found in a variety of cells and tissues, including the heart. Its main function is to regulate the metabolism of carbohydrates and proteins along with regulation of water and electrolyte balance in the body.

## Introduction

The adrenocortical layer produces corticosterone in rodents under the influence of adrenocorticotrophic hormone (ACTH). Mammals typically possess two adrenal glands; one located superior to each kidney (adrenal or supra renal) (Barrington 1963). The adrenal gland weighs on average 4–6 g and measures 4–6 cm long and

2–3 cm wide (McMINN 2003). Each limb normally measures <5 mm in width and the body should measure <10 mm in width (Sutton 2003; Prokop and Galanski 2003). Proportionately, the adrenal size is larger in neonates and infants, being almost one-third of the size of the kidney (Prokop and Galanski 2003). Each adrenal gland has two distinct structures, the outer adrenal cortex and the inner medulla, both of which produce hormones. One of the main functions of the adrenal cortex and the gonads is steroid hormone synthesis. The process in which specialized cells in specific tissues synthesize steroid hormones is generally referred to as steroidogenesis. Steroid hormones can be roughly divided into five groups according to their physiological behavior: adrenal mineralocorticoids, which regulate the salt balance and maintain blood pressure; glucocorticoids, which regulate carbohydrate metabolism and manage stress; progestogens and estrogens, which are mainly produced by the ovaries and regulate reproductive function and secondary sex characteristics in the female; and androgens, which are mainly testicular in origin and are essential for fertility and secondary sex characteristics in the male. These all share certain structural similarities and arise from a common series of pathways. Cholesterol is the precursor for all the steroid hormones, and although it can be synthesized *de novo* from acetate, most of the cholesterol needed is derived from plasma low density lipoproteins (LDL). Tropic hormones also stimulate the uptake of LDL cholesterol in addition to stimulating steroidogenesis. Most of the steroidogenic enzymes belong to the cytochrome P450 oxidation group, among which five enzymes are involved in adrenal steroidogenesis: P450scc

(side chain cleavage), P450c11 (11-hydroxylase), P450c17 (17- $\alpha$ -hydroxylase), P450c21 (21-hydroxylase), and P450aldo (aldosterone synthase). The first two of these are located in the mitochondria and the last two in the endoplasmic reticulum. In addition, P450aro mediates the aromatization of androgens to estrogens in the gonads. All steroid hormones are synthesized from the same precursor, cholesterol, but the end product depends on the complement of enzymes present in the tissues (Miller and Auchus 2011). Corticosterone is the precursor molecule to the mineralocorticoid aldosterone, one of the major homeostatic modulators of sodium and potassium levels in vivo (Fig. 1).

## Discovery

Corticosterone-like substance was identified by Mason et al. in the year 1937 while working with adrenalectomized dogs. In the early 1920s, Dr. Edward Kendall, a biochemist interested in endocrinological disorders, with the assistance of Drs Phillip Hench and Charles Slocum, extensively researched the adrenal gland and injected a part of adrenal extract (later known as cortisone) to 14 patients which ultimately alleviated rheumatoid arthritis leading to the receipt of the Nobel Prize in Medicine in 1950 (Kendall 1951).

## Corticosterone Biosynthesis

Adrenal glomerulosa cells mainly synthesize and secrete the mineralocorticoids, while the adrenal fasciculata cells synthesize and secrete the

(8*S*,9*S*,10*R*,11*S*,13*S*,14*S*,17*S*)-1,7,8,10,11,12,13,15,16,17-decahydro-11-hydroxy-17-(2-hydroxyacetyl)-10,13-dimethyl-2*H*-cyclopenta[*a*]phenanthren-3(6*H*,9*H*,14*H*)-one

**Corticosterone, Fig. 1** Corticosterone

glucocorticoids cortisol (in humans) and corticosterone (in rodents). The first, rate-limiting step in the synthesis of all steroid hormones is the conversion of cholesterol to pregnenolone. In mitochondria this involves three distinct reactions, which are mediated by a single enzyme, P450scc, the activity of which is not the critical factor, but rather the supply of the substrate cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane where the P450scc enzyme is located (Chapman et al. 2005).

Absence of P450scc activity results in an inability to synthesize any steroid hormone and leads to death due to mineralocorticoid deficiency. Patients with a lack of P450scc can be treated with glucocorticoid and mineralocorticoid steroid hormone replacement if diagnosed early enough. Pregnenolone may subsequently undergo one of two conversions. It may be converted by  $3\beta$ -HSD to progesterone, which is the first biologically important steroid in the pathway, or else it may undergo  $17\alpha$ -hydroxylation mediated by P450c17 to yield  $17\alpha$ -hydroxypregnenolone. Progesterone can also be hydroxylated by P450c17, resulting in  $17\alpha$ -hydroxyprogesterone. P450c17 has two activities, that of a  $17\alpha$ -hydroxylase and that of a C-17,20 lyase capable of breaking up the C-17,20 carbon bond of  $17\alpha$ -hydroxypregnenolone or  $17\alpha$ -hydroxyprogesterone, yielding dehydroepiandrosterone (DHEA) or androstenedione, respectively. P450c17 is a key branching point in steroid hormone synthesis, directing pregnenolone toward the sex steroids (both hydroxylation and cleavage activities of the enzyme), the glucocorticoids (only hydroxylation), or the mineralocorticoids, if neither of the enzyme activities is participating. After the synthesis of progesterone and  $17$ -hydroxyprogesterone, P450c21 can hydroxylate these steroids at the 21 position, resulting in deoxycorticosterone and 11-deoxycortisol, respectively. The final step in the synthesis of adrenal mineralocorticoids, and glucocorticoids is mediated by P450c11, which also mediates the final steps in the synthesis of aldosterone from deoxycorticosterone. When the P450c21 step is impaired, cortisol synthesis decreases, leading to overproduction of ACTH. Adrenal steroid synthesis is stimulated in this

condition and  $17$ -hydroxyprogesterone is converted to androstenedione and further to testosterone, leading to severe virilization of the female fetus. This disorder is known as congenital adrenal hyperplasia (CAH). Mutations in StAR cause lipid CAH, which disrupts the synthesis of all adrenal and gonadal steroids. Affected genetic males are born with normal female external genitalia (Miller and Strauss 1999; Stocco 2001).

### Hypothalamic-Pituitary-Adrenal (HPA) Axis

The HPA axis, which has traditionally been seen as the body's "stress system," and which ultimately controls levels of cortisol and other important stress related hormones, is generally underactive in people suffering from chronic fatigue syndrome (CFS) and burnout. New research is beginning to show that the HPA axis should instead be thought of as the body's energy regulator, as it is ultimately responsible for regulating many of the hormones, nervous system activity, and energy expenditure in the human body, as well as modulating the immune system and the digestive system. In CFS and burnout the HPA axis tends to be underactive, which is likely in many of the various physical and mental symptoms associated with these conditions. Under normal condition, the adrenal glucocorticoids, the end product of the HPA axis, provide a front-line of defense against threats to homeostasis (e.g., stress).

### Interrelationship between Male Gonadal and Adrenocortical System

These two axes, HPA and HPG, show significant similarity in terms of their regulation mechanisms. The hypothalamic central nervous system discharges GnRH and adrenocorticotropin releasing hormone (CRH), which is transported to the anterior pituitary, where they stimulate the gonadotrophs and corticotrophs, respectively. In response to stimulation, these cells in turn secrete the gonadotropins (FSH, LH) and ACTH. Under normal conditions, the hypothalamic-pituitary-adrenal (HPA) axis maintains frontline of defense

against stress. On the other hand, chronic HPA drive and glucocorticoid hypersecretion have been implicated in the pathogenesis of the several forms of systemic, neurodegenerative, and affective disorders. HPA axis is influenced by gonadal alteration. Functional cross-talk between the gonadal and adrenal axes is due to the interactive effects of sex steroid and glucocorticoids. This is the possible explanation why several stress-linked diseases are sex-dependent. Imbalance of one endocrine system is not without the effects on other. The adrenal axis regulates gonadal function and reproductive behaviour by modulating various components of hypothalamo-pituitary-gonadal (HPG) axis, including sex steroid release (Dallman, 1993).

In humans and rodents, stress and high doses of glucocorticoid generally disrupt all aspects of HPG function (Tilbrook and Clarke 2006). Conversely, estrogens and androgens, which form the basis for sex and individual differences in HPA function, act on several levels of the HPA axis, including adrenocorticoid synthesis, stress-induced ACTH, and glucocorticoids release. In addition to regulate the positive feedback of the HPA axis, several *in vivo* studies indicate sex differences and implicate sex steroid effects on glucocorticoids-mediated negative-feedback strength in rat (Kovács et al. 2000). This would suggest a probability for gonadal and adrenal interaction at genomic and cellular levels. Moreover, androgen and glucocorticoid receptors are capable to regulate transcription by physically interacting each other. Several brain regions, mostly hippocampus, amygdala, brain stem, several hypothalamic nuclei, show both sex and adrenal steroid receptors and functional connectivity to the HPA axis (Viau 2002).

Sex differences in both basal and stress-induced HPA activity are noticeable in a variety of species, in which males typically show lower ACTH and glucocorticoid levels under both conditions (Viau 2002). These sex differences in HPA function are credited partially to inhibitory effect of testosterone in males. ACTH and corticosterone responses to acute stress in the male rat are increased by gonadectomy, and this effect is

reversed with the replacement of testosterone or 5 $\alpha$ -dihydrotestosterone (5 $\alpha$ -DHT) (Viau 2002). This suggests that the inhibitory effect of testosterone in males on HPA function is mediated by an androgen receptor-mediated effect. So, simultaneous assessment of gonadal and adrenal activity bears great therapeutic as well as diagnostic potential in various diseases.

### Functional Defects of Corticosterone Secretion

Congenital adrenal hyperplasia due to 17- $\alpha$ -hydroxylase deficiency results from a defect in gene CYP17A1 in humans that is responsible for coding the enzyme 17 $\alpha$ -hydroxylase which results in decreased synthesis and secretion of corticosteroid with concomitant rise in mineralocorticoid production. Symptoms include hypogluccorticoid production, ambiguous genitalia in males, and failure of the ovaries to properly function during puberty in genetic females with features of hypokalemic hypertension (Yanase et al. 1992).

Secretion of corticosterone and cortisol is ACTH dependent and correlating high levels as in Cushing's disease and ACTH producing tumors; on the other hand, low concentrations may lead to ACTH deficiency and panhypopituitarism (Norris and Carr 1990). Corticosterone has also been shown to be decreased in 3 $\beta$ -hydroxysteroid dehydrogenase deficiency and 11 $\beta$ -hydroxylase deficiency; both of which are important rate-limiting enzymes in the steroidogenic pathway (Simard et al. 2005).

### Prognostic Value of Corticosterone

Corticosterone has high prognostic importance in certain diseases like in cancers (De la Roca-Chiapas et al. 2016) also in circadian and reproductive cycles of animals (Atkinson and Waddell 1997). However in some forms or the other, it is not used as medicine for clinical treatment purposes.

## Corvids

Claudia A. F. Wascher  
Department of Biology, Anglia Ruskin  
University, Cambridge, UK

## Synonyms

[The crow family](#)

## Definition

A corvid is a member of the passerine bird family Corvidae, which includes crows, magpies, ravens, jays, treepies, choughs, and nutcrackers.

## Introduction

The Corvidae family includes approximately 125 species and is part of a bigger group of more than 700 oscine passerine species, called Corvoidea, which, for example, includes birds of paradise and shrikes. Corvoidea originated in the area of Papua New Guinea and colonized the rest

of the world during the mid-tertiary, 25–40 million years ago (Jönsson et al. 2011). Today, corvid species are distributed worldwide except the southern tip of South America and the polar ice caps. They inhabit harsh environments such as mountainous regions, but also thrive in urban areas. Corvids are of broad significance for behavioral and ornithological research not only because of their ability to adapt to diverse habitats but also because of their great variability and flexibility in their social system. Corvids are renowned for their large brains and their remarkable cognitive skills in social and physical contexts. Describing similarities in cognitive abilities between birds and mammals is of special interest as the large phylogenetic separation suggests independent evolution of similar skills in certain ecological and social environments in distantly related species. The “Corvid Literature Database,” a project with the aim to record all publications on corvids, lists more than 8000 publications (<http://www.corvids.de/cld/search.php>; Droege and Töpfer 2016).

### Foraging Ecology and Physical Cognition

Physical cognition refers to cognitive skills, which facilitate processing information about the physical world, often related to complex foraging tactics, such as tool use, caching, or extractive foraging. Corvids are omnivorous generalists, feeding on many different plants and animal species, including fruits, seeds, roots, insects, worms, birds’ eggs, small vertebrates, and carrion. In response to unpredictable environments, such as seasonal availability of food, the evolution of extractive foraging is favored, defined as the act of locating and processing embedded food. Many corvid species are extractive foragers and, for example, drop nuts or mussels to remove them from their shells, use tools to extract grubs from wooden logs, or predate on eggs of burrow nesting seabirds.

Corvids evolved from a food-caching common ancestor, and most current species store and cache food for later consumption. Some species, for example, common ravens (*Corvus corax*) and

carrion crows (*Corvus corone*), scatter-hoard when competing for food with others, and recover caches rather shortly thereafter, whereas Clark’s nutcrackers (*Nucifraga columbiana*), Siberian jays (*Perisoreus infaustus*), and other long-term seed-caching species cache in order to survive long periods of food uncertainty. Food caching is generally associated with good performance in spatial memory tasks and increased hippocampal volume. Western scrub jays (*Aphelocoma californica*) do not only memorize where they cached food, but also possess a memory for the food type they cached (what), and when the cache was made, which is seen as evidence for episodic-like memory, facilitating species that cache easily perishable food, such as insects, to retrieve the food before degradation (de Kort and Clayton 2006). Further to having to protect stored food from degradation, many corvids developed strategies to protect their caches from pilfering conspecifics by, for example, caching out of view of potential competitors, caching less when being watched by others, or recovering caches to change cache sites. In the presence of conspecifics, ravens try to actively distract others and lead dominant individuals away from hidden food. Ravens have been shown to modify their cache protection in relation to whether or not a competitor has knowledge about the cache locations, and assess the competitive strategies of unfamiliar individuals by caching nonedible items. In an experiment on captive ravens, human experimenters either stole a nonedible object, which was previously cached by the focal raven, or the experimenter only looked at the cache site, but did not remove the object from the stash. The test subjects then modified their food caching behavior according to the experience made in these trials: In presence of the stealing experimenter, they cached more often out of sight of the experimenter and took longer to cache than in the presence of the other experimenter (Bugnyar 2013).

One aspect of physical cognition is reasoning about causal relationships, which cannot necessarily be perceived directly but must be inferred from the spatiotemporal relationships between objects. Whether animals possess the cognitive ability to reason about causal relationships

between objects is tested in support-relation tasks, for example, string pulling. In this task, animals are confronted with a food reward that is out of reach, but attached to an accessible horizontal string. Naïve corvids readily start to pull the string and perform a coherent sequence of actions, repeatedly pulling up and stepping on the string in order to lift and eventually reach the treat (Heinrich 2011). Another task to test whether animals understand causal relationships is the trap-tube paradigm. In this experiment, animals have to use a stick to push a food reward out of a tube, but the animal has to avoid pushing it into a trap inside the tube, because if the food falls into the trap, it is lost for the focal animal. New Caledonian crows (*Corvus moneduloides*), a species that naturally produces and uses tools in foraging contexts, can solve this physical problem by causal reasoning. Also rooks (*Corvus frugilegus*), nontool using corvids, were shown to solve the task in a modified version, in which a tool was already inserted into the tube, so that the focal animal was only required to pull or push the stick to move the food (Taylor 2014).

Several corvid species have been tested for object permanence, defined as the knowledge that an object still exists, even when out of sight or displaced. This is cognitively challenging because it requires continuous updating of representations of the unperceived object and its position while maintaining a stable representation of the stationary surroundings. Corvids, similar to primates and dogs, have been shown to master object permanence in an experiment with increasing complexity. At the start of the experiment, they had to find food hidden in one out of two containers, later on food was hidden and invisibly displaced, or in a final stage of the experiment hidden and successively displayed, all conditions in which the corvids could successfully find the food (Hoffmann et al. 2011). In relation to this, corvids have been tested for their ability to select a correct alternative by logically excluding other potential alternatives. A food reward was hidden in one of two possible locations and the subjects received different information by being shown the content of either one or both potential locations. Hence, when only the content of the unbaited

location was shown, subjects had to choose the opposite location to find the hidden food. Two caching corvid species, common ravens and carrion crows, were able to exclude the unbaited location and choose the baited one, whereas non-caching jackdaws (*Corvus monedula*) could not solve the task, indicating that within corvids, caching might be key in the evolution of exclusion performance (Mikolasch et al. 2012).

The cognitive ability to manufacture and use tools is seen as an advanced form of physical intelligence. Among nonhuman animals, chimpanzees, and New Caledonian crows are considered the most proficient tool users. New Caledonian crows manufacture different types of tools, for example, hooked twigs and stick tools, which they use to retrieve insects behind bark or from cavities in wood (Rutz and St Clair 2012). The cognitive underpinnings of tool use in New Caledonian crows have mostly been assessed in captivity. Crows are sensitive regarding the functionality of tools. When presented with ten stick tools of different lengths, crows avoided selecting unsuitable tools, which were too short to reach a food reward. New Caledonian crows can spontaneously solve a meta-tool task, in which they have to use a small stick as a tool to obtain a longer stick, which they can then use to retrieve a food reward (Taylor 2014). When crows were provided with materials to manufacture tools, they made tools appropriate in diameter to insert them into holes of differing sizes. Captive juveniles were found to manipulate objects during ontogenetic development, even before they actually use tools, and the motor patterns shown resemble components of tool use behavior in adult birds. Further, juvenile individuals, who received demonstrations of twig tool use by a human foster parent, manipulated and applied twigs more often than naïve counterparts. In a choice experiment, crows preferred to handle objects which have been manipulated by their human foster parent before, indicating that social learning might be involved in the development of tool use (Kacelnik et al. 2006). Recently, a second corvid species was discovered to use foraging tools, the Hawaiian crow (*Corvus hawaiiensis*). Within the family of corvids, New Caledonian crows and Hawaiian

crows are only distantly related but live under similar ecological conditions on remote tropical islands. This suggests that tool use in corvids is facilitated by ecological conditions, and has evolved at least twice in the family of corvids (Rutz et al. 2016).

## Social Life

Corvids express high variability in breeding systems and social organizations among species, as well as flexibility of the latter within species, depending on life history and ecological factors. Nonbreeding individuals of many corvid species form flocks, which consist of juvenile birds, adult individuals without a partner, or paired birds, which could not secure a territory. These nonbreeder flocks are characterized by fission-fusion dynamics, which means that the flocks vary in size and membership throughout the day; for example, large groups may be formed when foraging or roosting for the night, and smaller groups of variable compositions are formed when resting during the day. In order to successfully reproduce, most corvid species need to secure a territory, which is defended against conspecific competitors.

A particularly well-studied example of within-species flexibility in the breeding system depending on ecological factors is provided by the carrion crow. Carrion crows breed in male-female pairs in most European populations; however, in at least two populations in Spain, birds have been described to breed cooperatively in extended family groups of three to nine individuals, in up to three-quarter of the territories (Baglione and Canestrari 2016). Territories in these regions are of particularly good quality, for example, in terms of food availability, and are therefore defended year-round. Instead of joining nonbreeding flocks, offspring delay their dispersal from natal territories and stay with their parents for an extended period, often for a couple of years, and help their parents to raise offspring, i.e., cooperative breeding occurs. Whether the breeding system is determined by genetic or environmental factors was tested in an experiment for

which eggs were transferred from a cooperatively breeding population of carrion crows in northern Spain to a noncooperatively breeding population in Switzerland. Juveniles hatched in northern Spain delayed dispersal and became helpers, whereas the juveniles hatched in Switzerland dispersed from their foster parents' territories during their first winter. This strongly suggests that environmental conditions, rather than a genetic component, drive the expression of cooperative breeding. Indeed, in territories which were experimentally supplemented with food year-round, offspring was more likely to delay dispersal and become helpers than in control territories (Baglione and Canestrari 2016).

Cooperative breeding has been described in 27 out of 84 corvid species with known breeding system. It is correlated to geographic zone, with a higher prevalence in southern latitudes (Ekman and Ericson 2006). Other species such as Siberian jays or New Caledonian crows live in family groups but no helping occurs. Although in a majority of cases family groups consist of adult individuals and their retained offspring, 26% of groups in Siberian jays (Lillandt et al. 2003) and 61% of groups in Carrion crows contain immigrants from other territories (Baglione et al. 2003). Flexibility in social organization can also be found within one population, as exemplified by Azure-winged magpies (*Cyanopica cyanus*). While Azure-winged magpies from a population in central Spain breed in distinct territories, Azure-winged magpies in South Korea breed in colonies. Depending on weather conditions, percentage of nests assisted by helpers varies from 27 to 73 (Valencia et al. 2003). Colony living also occurs in other species of corvids, such as rooks, jackdaws and pinyon jays (*Gymnorhinus cyanocephalus*), which form large flocks year round and also, reproduce in these groups.

Within their social groups, corvids form valuable social relationships, characterized by spatial proximity, high levels of tolerance, low frequencies of aggressive interactions, and high frequencies of affiliative behaviors. These social relationships are preferably formed between kin, but also nonkin, individuals, and ultimately might result in a long-term monogamous pair

bond. Social relationships help individuals to gain access to resources such as food or territories, and individuals in social relationships are more likely to win agonistic encounter through coalitional support (Bugnyar 2013). Additionally, to these selective relationships which help individuals to cope with the challenges of living in groups, also monogamous pair bonds in corvids are characterized by complex social interactions, with high levels of cooperation, coordination, and affiliation, which could have required the evolution of advanced cognitive skills, necessary to maintain long-term pair bonds (“relationship intelligence”: Emery et al. 2007).

Especially in the context of food, corvids are highly competitive. Corvids usually form linear dominance hierarchies, in which individual A is dominant over individual B, individual B is dominant over individual C, and so on, and males generally outrank females. Some species show postconflict affiliation between former opponents after aggressive encounters, similar to so-called reconciliation behaviors described in several primates, e.g., macaques and apes. Postconflict affiliation is seen as an important mechanism to reduce the costs of aggression, for example, by reducing the stress of individuals involved in agonistic encounters or by decreasing the likelihood of redirected aggression. While in some species, e.g., rooks and Eurasian jays, no reconciliation occurs between former opponents, both the initiator and receiver of aggressive encounters engage in postconflict affiliation with uninvolved third-party individuals such as their pair-partner (Emery et al. 2007). This form of postconflict affiliation is termed consolation. In common ravens, conflicts are usually followed by consolation from uninvolved bystanders and reconciliation between former opponents (Bugnyar 2013). Generally, the relationship between individuals plays a significant role and both reconciliation and consolation occurs more often between individuals who share a valuable relationship. Common ravens in valuable relationships support each other in aggressive encounters, i.e., coalition formation. However, they were also shown to intervene in

affiliative interactions of other individuals, with aggression or by placing themselves between the affiliating individuals. This behavior is seen as an endeavor to prevent other individuals from gaining benefits from forming coalitions, which might be turned against themselves (Massen et al. 2014a).

The challenges of living in social groups are considered as a main driving force for the evolution of advanced cognitive skills (Humphrey 1976). Individuals in groups need to individually recognize group members, track relationships between individuals and others’ rank positions, as well as update that information when circumstances change. Given the complexity and flexibility of the social system in corvids, they became a prime avian model for the study of social cognition, and are well studied comparatively. In order to investigate whether living in groups in corvids accounts for enhanced cognitive skills, several corvid species with different social organization have been tested for their ability to infer and track third-party relationships. It is hypothesized that individuals living in complex groups base their knowledge about relationships of other individuals in the group on transitive inference; for example, A is dominant over B and B over dominant to C, then A is likely to be also dominant over C. The ability for transitive inference allows individuals an assessment of specific relationships, even if not all individuals have been observed interacting with each other. Pinyon jays, which live in colonies of up to several hundreds of birds, learn dyadic relationships faster and more accurately compared to pair-breeding western scrub-jays, and are better in transitive inference (Bond et al. 2003). In order to test whether common ravens possess an understanding of third-party relations, they were subjected to a playback experiment, presenting simulated social interactions of group members to a focal bird. Compared to ordinary vocal interactions between dominant and subordinate individuals, focal birds showed more self-directed behaviors, which are considered an indicator of stress, when confronted with unexpected vocal interactions, i.e., dominant calls by a subordinate individual followed by submissive calls emitted by a dominant individual. The

difference in behavioral responses by the focal individuals indicates that ravens recognize third-party rank relationships of individuals they regularly interact with (Massen et al. 2014b).

In various contexts, such as foraging and predator avoidance, corvids use information provided by conspecifics. Communal roosts of corvids can function as information centers, with naïve individuals gaining information about feeding sites from knowledgeable individuals. Departures from night roosts are highly synchronized, with most individuals departing in one direction and knowledgeable individuals leading the way (Heinrich 2011). When confronted with novel objects or food sources which they have not encountered before, corvids are generally fearful, or “neophobic”. Rooks and jackdaws consume novel food only when a demonstrator foraged on this food type before (Greggor et al. 2016), indicating social facilitation of foraging decision. Neophobia can be adaptive as it provides protection against potential risks associated with objects and foods; however, it also limits exploration, innovation, and learning. Social contexts strongly affect neophobia. Common ravens approach food sources quicker on their own, compared to when being in dyads (Bugnyar 2013), whereas in groups of cooperatively breeding carrion crows, subordinate individuals only approach food sources which have been explored by dominant individuals before (Chiarati et al. 2012). Social learning of information about dangerous humans was demonstrated in an experiment on wild American crows (*Corvus brachyrhynchos*). Humans wore a distinctive mask when capturing and banding crows, in order to associate the mask (face) with danger for the crows. Adult crows quickly learned to associate the masks with threat and responded to it with scolding, a typical antipredator response in crows. The information about the dangerous humans wearing masks quickly spread within the population of crows, and also individuals who never experienced any bad experience associated with the masks themselves started to scold at it, even up to 1.2 km from the initial capturing sites, and 5 years after the start of the experiment (Marzluff and Angell 2013). This illustrates not

only the broad and efficient spread of social information within a population, but also its long-term persistence. As social transmission occurs between individuals that observe or interact with each other, information transmission is strongly linked to characteristics of the social network. Common ravens were found to preferably observe affiliated individuals and siblings, and the observation network predicted the transmission of information in a novel foraging task (Kulahci et al. 2016).

One key question of research on cognition in corvids is whether individuals have an understanding of each other’s knowledge. Theory of Mind is the ability to attribute mental states such as intents, desires, and knowledge, to one-self and other individuals. Theory of Mind allows individuals to understand that others have mental states and perspectives that are different from their own. Whether or not nonhuman animals and prelinguistic children possess a Theory of Mind proves difficult to assess. A series of cognitive precursors have been identified; one of them is self-recognition, as it is thought to show self-awareness. Self-recognition in nonhuman animals can be assessed via studying the behavior of an animal in response to its reflection in a mirror. Usually, the focal subject is fitted with an unusual mark, such as a colorful spot on its forehead. Most animals confronted with a mirror show social behavior, usually aggressive displays, indicating that the image in the mirror is perceived as an unknown, potentially dangerous conspecific. Some primate species confronted with their mirror image show self-directed behaviors, especially trying to remove or investigate the mark, which indicates that they recognize themselves in the mirror. Similar to great apes, Eurasian magpies (*Pica pica*) show mirror-induced self-directed behavior and started to preen and scratch themselves, indicating that they are self-aware.

A second cognitive prerequisite of Theory of mind is the ability to understand that other individuals have mental states that underlie their actions. This ability is called “desire-state attribution” and has been tested in Eurasian jays (*Garrulus glandarius*), a monogamous corvid

species. During the breeding season, male Eurasian jays frequently share food with their pair-partner. In an experiment, jays have been fed with two different food types, wax worm or mealworm larvae. After eating either type of food for a certain amount of time, individuals started to show “specific satiety” against this type of food, meaning that they started to prefer the other food type. At the start of the experiment, females were given one type of food to eat and their male partners could watch their partners eating either wax worm or mealworm larvae. Later on, the male jays were given access to the two food types and they preferably fed their female partner with the food that the female had not eaten before. The males did so even when the food type the female preferred was in conflict with the male’s own desire. These results indicate that the male jays pay attention to what their female partner has previously eaten, and that they are sensitive to mental states and current food preferences of their pair-partners (Taylor 2014). The cognitive ability to take other individuals’ perspective and understand what others know and understand about the environment is tested in behavioral experiments in which focal individuals have to compete for food with individuals that have either seen where the food was placed, or did not see the location of the food. If animals are aware of what other individuals know or do not know, they should behave differently toward knowledgeable and not knowledgeable individuals. Common ravens were given the opportunity to place food caches in a testing compartment while either being observed by a conspecific or being unobserved during the caching. Afterward, the previously observing bird (knowledgeable individual) or an unknowledgeable bird was let into the test compartment, additionally to the focal individual. When a knowledgeable individual joined the focal raven, the latter retrieved more caches in order to eat the food, or recache it at a novel site, compared to when a naïve individual, which was unaware of the cached food, joined the room. This indicates that focal ravens behaved differently depending on whether or not the conspecific was knowledgeable of the location of food caches. However, it is unclear whether focal ravens

simply respond to behavioral cues given by the knowledgeable conspecifics. To test this, a further experiment was conducted in which the presence of a potential observer was simulated using a playback in a room adjacent to the testing compartment. Peepholes providing visual access to the test compartment were either open or covered, providing the opportunity to assess whether a conspecific in the adjacent compartment could potentially observe the testing compartment or not. Focal ravens protected their caches when visual access was provided via open peepholes, but not when peepholes were covered, indicating that they are aware that conspecifics could not know about the location of their caches in the latter situation (Bugnyar et al. 2016).

Various forms of cooperation can be observed in corvids; for example, common ravens reciprocate each other’s help in aggressive encounters (Bugnyar 2013), jackdaws and rooks share food (Emery et al. 2007), and Florida scrub jays (*Aphelocoma coerulescens*) coordinate their vigilance into a sentinel system, where one member of the group is standing guard in a prominent position while the rest of the group forages (McGowan and Woolfenden 1989). Cooperation often occurs between related individuals, i.e., nepotism, driven by kin selection. In Siberian jays, juvenile individuals delaying their dispersal and staying with their parents as a family group in their natal territory, benefit from vigilance and predator avoidance provided by their parents (Griesser et al. 2006). In cooperatively breeding carrion crows, adult males, who are also the most dominant individuals in a group, approach novel and potentially dangerous food sources first to explore them. Later on, they tolerate their own offspring at the food source and co-feed with them, whereas they attack group members which are unrelated immigrants (Chiarati et al. 2011). Further to kin selection, other explanations for the evolution of cooperation in nonhuman animals are reciprocal altruism, i.e., individuals help each other in order to receive help back in the future, and mutualism, i.e., individuals work together because all will profit from it. The underlying evolutionary mechanisms of cooperation in animals are investigated in laboratory experiments, using well-established

paradigms, such as the loose-string pulling or Prisoner's Dilemma paradigm, which aim at facilitating comparative studies in order to understand the evolution of cooperation in different species and taxa. Corvids have been shown to cooperate in various contexts when both cooperation partners benefit from the action. For example, rooks and ravens act together when tested in a loose-string pulling task, where two individuals have to simultaneously pull a string in order to move a board containing a food reward toward them. When given the choice to cooperate with an affiliated or not-affiliated individual, ravens preferred to cooperate with individuals they share a valuable relationship with (Asakawa-Haas et al. 2016). Notably though, rooks were not able to delay acting when they had to wait for their experimental partner, and also did not show a clear preference for an apparatus that could be operated individually, indicating that they did not seem to have understood the causalities of the task (Seed et al. 2008). In another cooperation task, New Caledonian crows successfully passed a stone to a partner in an adjacent compartment, so that the partner could then use the stone to trigger an apparatus that released food rewards into both cages. However, they also did not pass the control condition, testing for an understanding of the task, as they also dropped stones into the other compartment when tested alone (Jelbert et al. 2015). Therefore, it is not clear whether these experimental tasks provide valid tests of an understanding of cooperation in corvids, or whether individuals operate the devices simply because they learned that a certain action will provide them with a reward.

One paradigm frequently used to assess whether humans or nonhuman animals are capable of reciprocal altruism is the Iterated Prisoner's Dilemma task. In this task, two individuals are tested with each other, and each individual has a choice to either cooperate or defect. The payoff for the two individuals is based on both, the own choice and the opponent's choice. When both players chose to cooperate, both receive a medium reward, and when both players chose to defect, they both get a small reward. However, if one

player defects and one cooperates, then the defector gets a large reward, and the cooperator gets nothing. Blue jays (*Cyanocitta cristata*) tested in this paradigm failed to cooperate based on reciprocal altruism. Their poor performance in this task might be explained by blue jay's inability to cope with a delay of gratification (Stephens et al. 2002). Delay of gratification is the ability to postpone a response to an immediate reward in order to gain a more valuable reward in future, which presents a cognitive challenge for humans as well as non-human animals. The ability to successfully cope with delayed gratification is considered an essential cognitive prerequisite for reciprocal altruism, because this requires an individual to invest resources in the present in order to receive a future reward. When tested for their ability to delay gratification in a token exchange task, carrion crows and common ravens were given the opportunity to increase the quality of a reward after a given delay, by exchanging the initial token, which is a nonpreferred food item (e.g., a piece of bread), against a more preferred reward (e.g., grapes, sausage or cheese). In a similar task, subjects could increase the quantity of a reward by exchanging one piece of food against more pieces of the same food. Crows and ravens were able to cope with a delay of gratification of up to 10 min in order to increase the quality of the reward. However, they did not wait in order to increase the quantity of their reward, which is different to previously tested mammalian species such as primates and dogs (Hillemann et al. 2014).

Another cognitive prerequisite of cooperation is the ability to track efforts and payoffs of the interacting cooperation partners, and sensitivity to inequity. Being able to identify and correct unequal treatment is considered to facilitate successful long-term cooperation with unrelated individuals, through selection for collaborators and punishment for defectors. Inequity aversion was tested in carrion crows and common ravens, in a token exchange task. Birds were trained to exchange a nonedible token with the experimenter in order to receive a food reward. Subjects were then tested in pairs, experiencing inequity in work effort or reward quality. When the test subject had

to exchange the token in order to receive a reward, while its experimental partner received the reward as a gift, the test subject decreased its exchange performance. Similarly, when both, the test subject and its partner, had to exchange a token in order to receive food, but the test subject received a reward of lower quality than its partner (i.e., received less preferred food), it refused to take the reward more often compared to control conditions. These results indicate that carrion crows and common ravens are sensitive to inequity, and avoid interactions that yield uneven payoffs (Wascher and Bugnyar 2013). New Caledonian crows, however, show no sensitivity to inequity in reward distribution, indicating that while New Caledonian crows show elaborate cognitive skills in the context of physical cognition, such as the flexible tool use and causal understanding, they do not seem to have evolved elaborate cognitive skills in a social, cooperative context (Jelbert et al. 2015).

In order to successfully cooperate, individuals also need to be able to differentiate between reliable and unreliable conspecifics, and choose to interact with reliable ones. In a playback experiment, carrion crows learned to differentiate between reliable and unreliable unfamiliar individuals. Alert calls of unfamiliar carrion crows were either associated with a “dangerous” visual stimulus, i.e., a dead crow, in order to simulate a reliable alarm caller, or no visual stimulus, in order to simulate an unreliable alarm caller. Over the course of the experiment, crows started to call less frequent when listening to calls of the reliable compared to the unreliable stimulus individuals, indicating that crows are more attentive toward alarm calls of reliable birds, possibly in an attempt to gain as much information as possible in a potentially dangerous context (Wascher et al. 2015).

Vocal communication plays an important role in the social life of corvids. Corvids are open-end vocal learners, which mean they are able to acquire new calls throughout their live and not only in a specific sensitive period. Vocalizations can encode information about the calling individual, e.g., its sex, dominance status, or individual

identity, which potentially facilitates individual recognition. Large-billed crows can individually recognize group members based on their vocalizations (Kondo et al. 2012) and common ravens not only recognize conspecifics’ call, they also memorize the status of their social relationship with the caller for a number of years. In a playback experiment, common ravens were confronted with calls from unfamiliar individuals, and with calls of former group members, from which they had been separated for at least 3 years. The birds did not only differentiate familiar from unfamiliar calls, but also responded differently depending on the previous relationship with the calling individual. In response to the playback, ravens’ vocalizations were different when a former affiliated individual was played back compared to calls in response to a former foe (Bugnyar 2013).

Generally, vocal communication in corvids plays an important role in coordinating activities and providing information about the environment, e.g., presence of predators or food. Pair-bonded carrion crows and rooks use synchronized vocalizations in aggressive contexts or during territorial defense, and coordinate their behaviors and body positioning. This has been suggested to be a cooperative display increasing the effectiveness of the territory defense and strengthening the pair bond (Emery et al. 2007). Ravens use loud calls, so-called “haa-calls,” to attract conspecifics in a foraging context, and to coordinate group movements. “Haa-calls” are likely to be functionally referential signals conveying information about food quality and quantity (Heinrich 2011). Additional to distinct call types, individuals can produce numerous variations in call types, and produce complex sequences containing different call types or call variations. Siberian jays emit 14 different call types in response to predators, and encode information about how dangerous the predator is in both calling rate and call types used. Two specific call types were only emitted in response to seeing a hawk, and three call types were only used in the presence of an owl. Call types in response to a hawk also differed depending on whether the predator was perching, attaching, or searching (Suzuki 2016).

## Bird Brains?

In recent years, studies on corvids helped to shed light on a better understanding of avian brain architecture underlying complex cognitive skills. Compared to primates and other mammals, corvids have a smaller absolute brain size; however, corvid brains contain on average twice as many neurons in the pallial telencephalon (Olkowicz et al. 2016). The classical view that complex cognitive skills require a cortex, which is only present in mammals but not in other taxa, was replaced by recent neurobiological findings of homologous structure in avian forebrains. The avian Nidopallium caudolaterale is the functional equivalent to mammalian prefrontal cortex, a multimodal center processing various cognitive skills such as associative learning, quantity discrimination, audio-visual stimulus associations across time, abstraction of general principles (Nieder 2017), and tool use (Mehlhorn et al. 2010). Also, emotional stimuli are processed similarly in corvids, humans, and other vertebrates. Using neuroimaging technology, American crows' brain activity was studied in reaction to exposure of pictures of human faces, which have previously been associated either with threat (being captured) or caretaking, in order to elicit emotions. In response to viewing the pictures, amygdalar, thalamic, striatal, and brainstem regions have been activated in the crows (Marzluff and Angell 2013). This is similar to neuronal circuitry underlying emotional processing in humans and other vertebrates. Neurological data from corvids strongly points toward convergent evolution of functionally similar but anatomically very different forebrain structures across vertebrates.

## Conclusion

In recent years, corvids have become an important avian model system to study the evolution of complex cognitive skills. Similarity in cognitive performances between primates and corvids suggest a convergent evolution of certain cognitive skills in birds and mammals. Advanced cognitive

skills in corvids seem to have evolved from both, requirements in the ecological and the social environment. Corvids adapted to a wide variety of environments, are innovative problem-solvers, and possess several requirements for successfully managing multiple social relationships. Although research on a few corvid species has been flourishing in past years, there is yet much work needed to understand the evolution of sophisticated cognitive skills in corvids. From the more than 120 species of corvids, detailed studies of the behavior and cognition is only available for about 10–20 species, which all show quite remarkable behaviors or abilities, such as tool use, cooperative breeding, and advanced cache-protection strategies. In order to comprehensively understand the evolution of complex behaviors and underlying cognitive traits, comparative studies of the ecology and social behavior of different species are needed.

## Costs of Group Living

Florence Landry and Ming Fei Li  
Department of Anthropology, University of  
Toronto, Toronto, ON, Canada

## Introduction

The occurrence of group formation has been recorded in many animals across diverse taxa. Such aggregation can take various forms creating a diverse array of group configurations that differ in the number of individuals, the stability of a

group's composition, the frequency of physical contact, social interactions, as well as spatial proximity and the duration of the group over time. The definitions of group living in the literature differ based on what behaviors are required from members in order to form a "group" (Krause and Ruxton 2002). That being said, every definition of group living usually require that animals need to show some degree of spatial proximity over time to be considered as a group. Wilson's (2000, p. 585) definition states that a group is "any set of organisms, belonging to the same species that remain together for a period of time while interacting with one another to a distinctly greater degree than with other conspecific organisms."

Theories on ecological pressure have proposed that the dynamic between benefits and costs for group living drove group formation to evolve independently in different taxa. Indeed, groups should occur when its benefits for the fitness of an individual outweigh its costs. The benefits and costs that arise from ecological pressure can be broadly separated into three categories: foraging and access to resources, defense from predators, and access to mates. The benefits of group living commonly include an increase in food searching efficiency, decrease in risk of predation, and increase in mating opportunities. On the other hand, the costs of group living usually include an increase in intragroup resource competition for both food and reproductive opportunities, as well as an increase in exposure to diseases and parasites. However, the presence of these costs and benefits, as well as the extent to which they can affect an individual in a group, is often influenced by the size of its group.

### Within-Group Competition

One of the main costs of living in a group is the increase in competition within the group among its members for access to resources (i.e., food, mates). Competition can be categorized into contest and scramble competition (Nicholson 1954). Contest competition occurs when the resource is distributed in a manner that allows it to be

defended or monopolized by certain individuals. Oftentimes, the winners of contest competitions are dominant individuals who can aggressively defend a resource from other group's members and subsequently obtain a larger share (van Schaik 1989). Scramble competition occurs when the resource is dispersed and shared by all members of the group. In scramble competition, the resource cannot be monopolized by the dominant individuals. Since the resource is limited in quantity, as group size increases, scramble competition will increase; thus scramble competition is often density dependent (van Schaik 1989). The type of resource greatly affects the kind and degree of competition. For example, leaves are generally more dispersed and ubiquitous than fruits, so animals with a primarily folivorous diet typically experience more scramble competition while frugivores and insectivores experience more contest competition.

The ecological-constraints model states that the upper limit of group size is constrained by costs associated with feeding and foraging. The bigger the group, the faster resources will get depleted, and the group will have to incur greater costs in order for all group members to satisfy their daily energy requirements. As group size increases, so will the group's day range and travel costs since it will need to forage greater distances to find food. In two groups of red colobus (*Procolobus badius*), a species that predominantly feed on leaves, it was found that the larger group travelled more, rested less, and had larger day and home ranges than the smaller group (Gillespie and Chapman 2001). Results from five groups of ursine colobus monkeys (*Colobus vellerosus*) concur with findings from the red colobus as day range, home range, and percentage of time spent feeding increased with group size (Teichroeb and Sicotte 2009). In frugivorous primate species, larger groups were also found to have travelled further and spent more time feeding than smaller groups (Majolo et al. 2008). These results suggest that larger groups, independent of diet composition and type of food competition, suffer greater within-group competition than smaller groups (Majolo et al. 2008). Furthermore, female fecundity was found to be lower in larger than in smaller

groups, which reflects the negative effects that bigger group sizes have on group members' physical states and ability to meet their daily energy requirements (Majolo et al. 2008).

Although the main cost of group living is food competition, there are additional costs related to feeding and foraging. Firstly, groups that devote more time to feeding and foraging trade-off on time that can be spent to strengthen social bonds, which is important for group-living animals. For example, grooming in primates is an affiliative behavior that helps strengthen social bonds, aids the formation of alliances, and functions as a form of reconciliation following agonistic encounters. If a group spends more proportion of their day feeding and foraging, then there is less time available for grooming. Similarly, there is a trade-off for time spent resting, which is important for the digestion of fibrous food, especially for folivores (Majolo et al. 2008). Secondly, individuals in larger groups have to travel greater distances to find food, which increase their risk of encountering predators in unfamiliar areas beyond their home range (Terborgh and Janson 1986). Larger groups are also more easily detected by predators due to increased noise and visibility (Terborgh and Janson 1986). Furthermore, an individual's spatial position within the group reflects the variation in predation risk. Individuals on the periphery of the group have a much higher chance of encountering predators compared to individuals adopting a more central position. In this sense, group members are in competition over preferred spatial positions to maximize safety from predators. In chacma baboons (*Papio ursinus*), dominant individuals occupied a more central position while feeding (King et al. 2011). Dominant members are able to engage in contest competition and displace subordinates from the center of the group. The predation risk associated with group living is also demonstrated by the tendency of nocturnal primates to forage individually in order to avoid being detected by predators that rely on sound to hunt (Clutton-Brock and Harvey 1977).

Another aspect of within-group competition that directly affects an individual's fitness is access to mates. In group-living animals, an

individual's social status in the group has important implications. In species with a marked dominance hierarchy, dominant individuals have fitness benefits in contest competitions over priority of access to both food resources and mating opportunities. Mandrills (*Mandrillus sphinx*) live in multi-male multi-female groups that display a dominance hierarchy, and there is intense male-male contest competition for access to fertile females. Using long-term data on a colony of mandrills, Setchell et al. (2005) found that alpha males were responsible for 94% of periovulatory mate guarding and accounted for 69% of offspring paternity. Thus, a major cost of living in groups is competition for mates which can result in disproportionate fitness costs for subordinate members due to reproductive skew favoring higher-ranking members. The alpha males also suffer group-living costs, since in mandrills, mate guarding became less effective and paternity decreased as the number of adult males in the group increased (Setchell et al. 2005).

Another cost of within-group competition is the possibility for exploitation of others' efforts, such as in the case of kleptoparasitism, which is the stealing of a resource that had been obtained by another individual. Among group-living foragers, an individual can either actively search for food (the producer strategy) or join in to feed at a food patch that has been discovered by another group member (the scrounger strategy). The presence of scroungers in a group lowers the average foraging rate of the group and is a cost to group living (Vickery et al. 1991). Kleptoparasitism is advantageous for the parasitic individual who does not need to invest as much effort into securing food. However, the costs of kleptoparasitism are borne by nonparasitic group members. As a result, a cost of sociality and group living is the presence of "cheaters" and "freeloaders" that do not contribute proportionally to the efforts of the group.

### Increase of Parasite

The other main cost of group living that has received an increased of interest over the years is

the possibility that group living could increase parasite transmission and disease. Indeed, Alexander wrote in 1974 that “the prediction is compelling that group living animals will either be plagued more heavily with parasites and diseases than their solitary living close relatives, or they will be plagued with greater expense of time and energy, and greater risk, in reducing the attacks of such organisms.” Parasitism is still widely viewed as one of the primary costs of sociality that could have a role in limiting group size. Aggregation could facilitate pathogen transmissions, and animals living in larger groups, due to their higher local density, would experience a greater exposure to parasites than those living in smaller groups or solitary animals.

The fact that aggregation could increase parasite transmission is, however, dependent on both the ease with which the pathogen is transmitted from host to host and the host group’s characteristics. Parasites can be transmitted in multiple ways going from searching parasites that can infect their host by travelling between groups either on their own (i.e., using aerosolized transmission routes) or by using a mobile vector of a different species (i.e., vector-borne) to contagious parasites that require close contact to transfer between hosts and thus are generally restricted to within-group transmissions. Parasites can also be environmentally transmitted, usually through fecal-oral transmission or from contaminated water, ground, or food. Therefore, the types of transmission have a direct influence on whether an increase in parasite transmission will be associated with group living. More mobile transmitted pathogens are density dependent, where an increase in transmission should happen with an increase in population and parasites that require intense physical contact for transmission (e.g., sexual transmission) being independent of population size.

The interactions between the types of transmission and group size could then explain the differences found among social groups, populations, and species in terms of their levels of infestation and infection by parasites. Indeed, a larger group size may increase parasitism through several mechanisms, one of them being the local density

created by group living, which could favor the establishment of infections (Anderson and May 1982). Larger groups may also seem more attractive to both conspecific migrants, which could increase the possible arrival of migrants carrying an infectious disease (Brown and Brown 2004), and vectors, which could result in an increase in the percentage of individuals being infected by vector-borne parasites (Davies et al. 1991). Moreover, members of larger groups may also have more opportunities of interaction with other group members creating a possible increase in physical contact allowing again more opportunities for parasite transmission (Dunbar 1991). Finally, as larger groups deplete their food patches faster than smaller groups, these groups usually travel farther and increase the chance of infection through environmental transmission (Freeland 1979).

When looking into the literature, multiple studies have demonstrated a relationship between certain pathogens, their types of transmission, and group size. This confirms that certain pathogens are a cost associated with group living. Cote and Poulin (1995) presented a meta-analysis demonstrating consistent positive correlations between group size and parasitism rates for parasites transmitted by close contact or by a fecal-oral route but consistent negative correlations for searching parasites and no correlation for either parasite intensity or prevalence and host mobility. Patterson and Ruckstuhl (2013) found in their own meta-analysis similar results regarding the correlation between parasite transmissions and group size but were able to demonstrate a positive association with parasite intensity and prevalence, as well as an impact of host group mobility where the intensities of parasites did not increase with group size of mobile hosts. Rifkin et al. (2012) proposed for their part another meta-analysis also supporting the association between parasite infection and group size with an effect size varying between transmission modes but found an overall positive association for environmentally transmitted parasites, vector-borne parasites, and no association for searching parasites, which differs from previous findings (Cote and Poulin 1995; Patterson and Ruckstuhl 2013).

Empirical evidence for the associations between group size and parasitism are mixed. On the one hand, studies confirming the prediction can be found. For example, the prevalence of intestinal parasites in species of African artiodactyls increased with group size (Ezenwa 2004) and higher individual infestations of lice (*Colpocephalum turbinatum*) are found in larger groups of Galapagos hawks (*Buteo galapagoensis*) (Whiteman and Parker 2004). On the other hand, studies showing the opposite result are also present in the literature. For example, the intensity of parasitism by direct transmission was significantly higher in solitary species than in gregarious species among 12 species of Indian mammals (Watve and Sukumar 1995), while the level of ectoparasite infection in an intraspecific study of alpine marmots (*Marmota marmota*) living in larger groups was not significantly higher (Arnold and Lichtenstein 1993). Faced with these contradictions, certain researchers have started to propose that previous predictions of the relationship between parasitism and aggregation might be too simple, as the reality of group living might be more complex and therefore might not always bring a cost for individuals regarding parasites transmission.

### Anti-parasite Benefits of Group Living

While the relationship between aggregation, group size, and parasite transmission is well studied, the idea that group living might confer a benefit in terms of “anti-parasite transmission” to individuals, thus reducing the pathogen costs of being social, is more recent (Ezenwa et al. 2016). This idea, and the mechanism linked to it, could ultimately explain the variation found within studies that have looked into this relationship. Indeed, benefits of group living could fully or partially offset the transmission costs through either increasing the pathogen resistance of an individual or increasing its tolerance. Resistance to pathogens is usually defined as “a property of an individual, related to genotype or level of investment in immunological and behavioral traits associated with pathogen defense” (Ezenwa et al.

2016). Resistance refers then to two types of ability, one being the capacity to avoid or prevent infections, while the other is the ability to reduce either the number or growth of parasites once infected. Therefore, resistance acts by minimizing the level of infection for an individual and can involve immunological or behavioral mechanisms. The pathogen tolerance, on the other hand, refers to “any mechanism that can reduce the health or fitness impacts of pathogen infection” (Ezenwa et al. 2016). Through this mechanism, individuals could reduce the damage inflicted by pathogens, mitigating the association between parasite transmission and group size.

Group living through sociality could then have multiple ways to influence both resistance and tolerance to pathogens, including simple byproduct of sociality such as enhanced resource acquisition or more complex ones like promoting cultural transmission of parasite defense behaviors. Such behavior can take multiple form including allogrooming, which can facilitate the direct removal of parasites between group members that increases the resistance of an individual by reducing both transmission and exposure (Akinyi et al. 2013), or thermoregulation, such as huddling behavior that could help an individual to regulate or adjust their body temperature, which could provide pathogen tolerance benefits by improving their ability to cope with fever as an example (Medzhitov et al. 2012). Thinking about these possible anti-parasite benefits of group living may be useful to challenge our understanding of the cost of parasitism, as the extent to which the risk of parasite transmission increase with sociality is still unclear.

### Conclusion

Studies on the costs of group living challenge our understanding of one of the most fascinating phenomena in animals – sociality. Indeed, aggregation creates associations between individuals that allow them to form a group, which brings advantages to its members, such as a decreased risk of predation, enhanced efficiency when searching for resources, and better access to potential

mates for reproduction. However, a trade-off exists for animals in groups, where the presence of multiple individuals brings about an increase in competition for food and mating opportunities, as well as a possible increase in parasite infection and transmission. The costs mentioned in this paper are the most commonly stated ones. However, as social behaviors are being investigated more in depth, additional costs are starting to become apparent. One of them could be the consensus costs associated with the need to reach collective decisions for certain groups. Indeed, to access the benefits of group living, individuals must stay cohesive and maintain a degree of spatial and temporal coordination in their activities (Krause and Ruxton 2002). To do so, members may use consensus to reach a collective decision regarding the time and the direction of future activities. Such synchronization brings consensus costs for group members, since different individuals have different needs. In a group, individuals will differ in their characteristics like age, sex, and internal state (e.g., level of satiety, reproductive status) (Petit and Bon 2010), which create differences in their personal needs and make them differ in their optimal timing of activities or location preferences. Thus, consensus costs emerge from the necessity to compromise with other group members, where the fitness costs will increase with the difference between the optimal timing and movement location of an individual and the actual timing and destination of their group (Conradt and Roper 2010). More research will be needed to better understand the costs of living in a group.

- significance (Richardson et al. 1987). This occurrence results as an alternative conditioned response to the original stimulus (Lane 2009; Pearce and Dickinson 1975; Richardson et al. 1987). Counterconditioning can involve two distinct scenarios: (a) a previously appetitive response can become aversive (i.e., appetitive-to-aversive counterconditioning) or (b) a previously aversive response can become appetitive (i.e., aversive-to-appetitive counterconditioning). Counterconditioning consists of Pavlovian conditioning in which a previously neutral stimulus (NS) is paired with an unconditioned stimulus (US) to produce a conditioned response (CR). The NS becomes a conditioned stimulus after repeated pairings with the US. Counterconditioning successfully occurs when the original conditioned or unconditioned response is modified by replacing a cue from the original CS–US relationship, with one of opposite value.
- In the appetitive-to-aversive treatment, a conditioned or unconditioned stimulus first evoking an appetitive response, be it a CR or an UR, is paired with a stimulus evoking an aversive CR or UR. In other words, the CS or previously neutral stimulus is paired with an appetitive unconditioned or biologically relevant stimulus. This pairing results in the production of an appetitive conditioned response. Subsequently, the same CS is paired with a different US (aversive) to produce an aversive CR. If the US (aversive) condition is stronger than the US (appetitive), this produces a counterconditioning effect. The other possibility for counterconditioning is the aversive-to-appetitive transfer, which is opposite in nature to the previously described paradigm. In this condition, a CS is paired with an aversive US, to produce an aversive response. After producing this response, the same conditioned stimulus is paired with an appetitive as opposed to aversive US to produce an appetitive response. If the US (appetitive) condition is stronger than the US (aversive) condition, counterconditioning successfully occurs.

## Counterconditioning

Prescilla John

United States Army, New York, NY, USA

Counterconditioning occurs when a response to a stimulus is modified by pairing that stimulus with another stimulus of an opposite emotional

This form of Pavlovian conditioning allows for either an aversive or appetitive stimulus to create an association that is opposite from the originally

learned CS–US relationship. In this behavioral technique, the organism exhibits a CR to an aversive or appetitive stimulus which is then modified through the pairing of the original CS with a new US that is opposite in nature to the initial US. For example, in an aversive-to-appetitive counterconditioning paradigm, if an animal was forcefully placed in a cage in the past, they may have a hard time entering a cage in the future due to their prior learned aversive association with that cage. However, through counterconditioning, a more positive association can be formed with the cage. While entering the cage, the animal may be provided with a favored reward in order to change the previously acquired negative association with the cage to one that is more favorable. If the new CS–US association is stronger than the one that was originally acquired, this would result in counterconditioning. This counterconditioning effect is likely to make the animal feel more comfortable and assist in changing the animal's defensive response to entering the cage (Goldstein 1969; Pearce and Dickinson 1975).

Several researchers have suggested that Pavlovian counterconditioning occurs due to a reciprocal inhibitory interaction between positive and negative motivational systems (Bouton and Peck 1992; Estes 1969; Gray 1971; Klein 1969; Pearce and Dickinson 1975; Peck and Bouton 1990). Pearce and Dickinson (1975) have found that counterconditioning assists in modifying the aversiveness of a harmful cue. In their twofold Pavlovian counterconditioning experiment, rats received a series of shocks and food presentations. The researchers assessed the ability for the shock to become a reinforcer during a conditioned emotional response (CER). However the shock actually reduced suppression of the CER for rats in the experimental group (i.e., paired shock with food), while rats that received unpaired shock and food presentations had the opposite effect. In the second experiment, they found that when keeping food presentations constant, the reduction in suppression of responding became dependent on the magnitude of the shock. Similarly, Klein (1969) found that rats that were confined in a chamber with food became less fearful of a shock after counterconditioning in comparison to those who

were either confined in the chamber without food or not confined at all.

## Spontaneous Recovery in Counterconditioning

The recovery of a previously extinguished conditioned response following a rest period is referred to as spontaneous recovery (Pavlov 1927). Researchers have observed evidence of spontaneous recovery in counterconditioning paradigms (Bouton and Peck 1989, 1992; Bromage and Scavio 1978; Krank 1985; Scavio 1974). In this experimental setup, a conditioned stimulus (CS) is paired with an unconditioned stimulus (US). For each condition, the conditioned stimulus is paired with its respective unconditioned stimulus (i.e., shock or food/water). Based on literature findings, the CS begins to elicit a conditioned response to the second US by the end of this phase. However, the appetitive-to-aversive transfer has resulted in more equivocal results. The initial appetitive conditioning has been shown to hinder, facilitate, or have no impact on aversive conditioning in the second phase in comparison to the aversive-to-appetitive transfer condition.

Bouton and Peck's (1992) findings were mostly consistent with the previous literature. In this study, researchers examined the impact of the retention interval on performance in two counterconditioning paradigms, the aversive-to-appetitive transfer and appetitive-to-aversive transfer. The aversive stimulus used in this study was a shock, while food served as the appetitive stimulus. In both the aversive-to-appetitive and appetitive-to-aversive transfer conditions, spontaneous recovery of the originally acquired response was observed when rats were tested 28 days following the end of the second phase. This observation of recovery of responding in the aversive-to-appetitive condition suggests that interference in learning is not the only cause for spontaneous recovery.

However, research by Richardson et al. (1987) challenged these findings through evidence that counterconditioning can modify the retention of previously acquired fear responses in an aversive-

to-appetitive paradigm in rats. In this study, retention testing occurred the next day after counterconditioning in comparison to Bouton and Peck's (1992) experiment, which interpolated a 28-day retention period prior to testing. Based on these findings, it can be inferred that the time between counterconditioning and testing seems to play a pivotal role in its efficacy, while results from Bouton and Peck suggest that both retroactive and proactive interference play a role in the recovery of responding based on the observation that interference did not occur during learning, but instead took place at retrieval or performance.

## Counterconditioning in Psychotherapy

Counterconditioning processes have been utilized in clinical practice through a method referred to as systematic desensitization (Davidson 1968). Systematic desensitization is a technique used in the reduction avoidance behavior and is concerned with the aversive-to-appetitive transfer condition seen in counterconditioning. In systematic desensitization, an aversive imaginal (i.e., imagined) or in vivo (i.e., actual) stimulus is paired with anxiety competing relaxation techniques. This creates a hierarchy of exposure to the feared stimulus, while aiming to gradually reduce the individual's fear.

### Systematic Desensitization

As previously mentioned, systematic desensitization gradually exposes the organism to the fear-inducing stimulus and provides an opportunity for incremental habituation. It is a technique originally developed by Joseph Wolpe (1968) to modify a range of neurotic disorders. Wolpe (1968) found that cats could be desensitized to show less fear to previously feared conditions. In his study, cats were placed in a box and given electrical shocks. In the second phase of the study, he conducted a systematic desensitization task in which the cats were first fed from a distance and then incrementally closer to the box. Through this task, he found that the cats gradually displayed levels of reduced fear toward the box.

Since then Wolpe's systematic desensitization procedure has been used to treat individuals with anxiety and phobias by gradually exposing them to the fear producing stimulus while simultaneously allowing them to practice relaxation techniques in between exposures (Milenberger 2012). This is done either through imaginal or in vivo exposure, which is a paradigm that hierarchically exposes the person to levels of fear-producing situations. Systematic desensitization has also been modified for application to animals. The animal is gradually introduced to the aversive stimulus, which allows for habituation to each step before they are fully exposed to the fear-inducing stimulus (Clay et al. 2009). Some researchers have found that systematic desensitization is more efficient than counterconditioning in reducing separation-related problem behaviors in dogs (Acton 2012). However, research by Yin (2009) found that systematic desensitization works best for low level fears, while counterconditioning is most effective for higher levels of fears.

## Conclusion

Counterconditioning refers to the replacement of an originally conditioned response with the opposite conditioned response. Through counterconditioning, an organism can come to change their behavior as a result of a changed association that they have with stimuli in their environment. Research has shown that in both aversive-to-appetitive and appetitive-to-aversive counterconditioning paradigms, organisms are able to recover the first learned associations when tested after a retention period (Bouton and Peck 1992). These findings suggest that originally learned associations are not erased in light of new associations.

Counterconditioning has also been utilized in psychotherapeutic practice through procedures such as systematic desensitization (Davidson 1968). Several researchers have found that the originally acquired association is not destroyed when an organism is presented with a new US (Bouton and Peck 1989, 1992; Bromage and

Scavio 1978; Krank 1985; Scavio 1974), whereas other researchers have found that counterconditioning can modify some aspects of the originally acquired association (Richardson et al. 1987). Based on these equivocal findings, future research would benefit from exploring the relationship between counterconditioning and the length of the retention interval prior to testing.

## Countershading

Hannah M. Rowland

Max Planck Institute for Chemical Ecology, Jena, Germany

## Synonyms

[Dorsal pigmentary darkening](#); [Obliterative shading](#); [Optical flattening](#); [Thayer's law](#)

## Definition

Classically explained as an adaptation for camouflage, countershading describes the color pattern common among animals and is characterized by darker pigmentation on the side of the body that is most strongly illuminated.

## Introduction

Countershading is a color pattern that is observed in a diversity of taxa, across contrasting environments (Rowland 2009), and across ecological time (Smithwick et al. 2017). There are a number of reasons that countershading might evolve, including thermoregulation, protection against UV radiation, and defense against abrasion (Rowland 2009). The most researched hypothesis for the existence of countershading is that it enhances visual camouflage.

## The History of Countershading

The English naturalist Edward Bagnall Poulton and American artist Abbott Thayer independently proposed that the function of countershading is to enhance camouflage (Rowland 2009). Thayer went so far as to describe his hypothesis as “The law which underlies protective coloration.” Countershading was also adopted as a popular tactic in military camouflage during World War II (Behrens 1988).

## The Mechanism by Which Countershading Can Enhance Camouflage

If a uniformly colored object is illuminated from a particular direction, it reflects more light from the part of its surface facing the light than from the part facing away. Under sunlight, when light comes from above, a uniformly colored animal will appear brighter on its back and darker on its underside. This graded shading from light to dark is used by a number of animal species to perceive the shape of an object.

A countershaded pattern characterized by darker pigmentation of the regions of an animal's body that are directed toward the light cancels out the natural shading effect: a process known as self-shadow concealment. This can interfere with the perception of shape and make countershaded animals more difficult to detect

than uniformly colored animals (Cuthill et al. 2016; Penacchio et al. 2017).

## Evidence for the Concealing Effect of Countershading

Comparative analyses of the body color of primates (Kamilar 2009), ruminants (Allen et al. 2012), larval lepidoptera (Rowland 2009), and dinosaurs (Smithwick et al. 2017; Vinther et al. 2016) are consistent with countershading functioning as camouflage.

Computational models of countershading for crypsis simulate animals in realistic lighting environments and can predict optimal patterns for different weather conditions at a specific location and at specific times of the day and year (Penacchio et al. 2015). When artificial caterpillar-like prey with these putatively optimized countershaded patterns is exposed to predation, either in the field or in the lab, the rates of predation support the comparative evidence that countershading enhances camouflage by counterbalancing self-shadows (Cuthill et al. 2016; Penacchio et al. 2017).

## Countershading in Aquatic Environments

Some of the most compelling examples of countershading coloration are found in aquatic environments (Rowland 2009). The characteristics of light in air and water are different, as are the viewing angles between predators and prey (Kelley et al. 2017). This difference appears to have resulted in divergent mechanisms of concealment but similar phenotypes between the two environments: in aquatic environments, countershading appears to function by improving background matching rather than self-shadow concealment. The observed reflectance profiles of fish in different light environments do not match the optimal patterning for optimal self-shadow concealment: the body pigments of fish match the viewing background rather than concealing ventral shadows (Kelley et al. 2017).

## Conclusion

There is growing empirical and theoretical evidence to suggest that concealment of shadows is the primary explanation for the evolution of countershading. More research is required to reveal the mechanisms by which countershading affects predator perception. Whether nonhuman animals use shading as a three-dimensional cue or learn to detect a reflectance gradient remains unknown.

## Countersinging

Ednei B. dos Santos

GIGA – Neurosciences, University of Liege,  
Liège, Belgium

## Synonyms

[Coordinated singing](#); [Matched countersinging](#); [Song alternating](#); [Song overlapping](#); [Song-type matching](#); [Vocal duels](#); [Vocal interaction](#)

## Definition

Countersinging is a form of vocal interaction that occur between males of some territorial songbird species.

## Introduction

In *The Descent of Man and Selection in Relation to Sex*, Charles Darwin (1871) introduced his theory of sexual selection to explain the evolution of traits that function in attracting mates (often, but not always, manifest in males rather than in females) and in competing with rivals for access to them. He specifically considered the songs of male songbirds as a case in point which he proposed had evolved via sexual selection. Contemporary research largely confirms Darwin's

conjectures about bird song such that male songs are now generally viewed as “dual function” signals that play a key role in mating behavior. They are used by males to attract and stimulate the reproductive behavior of females, and to mediate competition with rivals. In some songbird species, songs are used to mediate conflicts over territorial spacing. These dyadic male-male vocal interactions are called countersinging. They can be classified as: time-specific responses, in which males coordinate the tempo of their own singing output to either overlap the songs of counterparts or alternate them, avoiding simultaneous singing; or pattern-specific responses, in which interacting birds can match the structural patterns, song types, of each other (Todt and Naguib 2000). Both time-specific and pattern-specific responses are associated with aggressiveness and escalated encounters between neighboring individuals.

### Choruses and Duets

Vocal interactions in songbirds are not limited to countersinging. However, interactions involving three or more individuals are usually not viewed as countersinging but as choruses. Songbird duets are yet another type of dyadic vocal interactions, but it involves mated pairs or parents and offspring. These additional forms of coordinated singing are outside the scope of this review.

### Song Alternating and Overlapping

The alternated production of auditory signals is a widespread phenomenon that can occur among individuals that share the same acoustic space. A clear advantage of alternating signaling is to avoid acoustic interference and increase signal detectability, allowing individuals to better listen to each other (Todt and Naguib 2000). Furthermore, the timing of songs during alternate singing can be indicative of variable degrees of aggressive intent. Hultsch and Todt (1982) studied alternate singing in nightingales and identified three different interaction strategies: *inserting*, *overlapping*, and *autonomous singing*. In dyadic interactions, inserters sing during the intervals between the songs of a counterpart. Overlappers start singing

before a counterpart has finished its preceding song. Autonomous singers do not adjust the timing of their songs to fit the singing output of counterparts.

Dabelsteen and collaborators (1997) investigated the functional role of song alternating and overlapping in male robins using an interactive playback approach. Research on countersinging has greatly benefited from the use of interactive playbacks. This technique allows researchers to manipulate in real time the stimuli used to test the vocal responses of study subjects. Hence, played back stimuli can be interactively modified as a function of the changing subject's behavior. Dabelsteen et al. (1997) results led to the conclusion that song alternating and overlapping are not random and indeed have functional value. In male robins, both patterns indicate aggressive intent but song overlapping signals a higher singer arousal than song alternating. Results from research in male robins, nightingales, and great tits indicate the existence of an escalation sequence that goes from song alternating to overlapping, then close range encounter, and finally an attack (Dabelsteen et al. 1997). Research in great tits (Otter et al. 1999) indicates that the outcomes of countersinging interactions are not only relevant to the two active singing participants but also to eavesdroppers. In this species, females eavesdrop male-male countersinging and might use these interactions to assess potential extra-pair partners. Females paired to males that received de-escalated treatments (song alternating) were less prone to visit neighboring territories than females paired to males that received escalated treatments (song overlapping).

### Song-Type Matching

Songs are stereotyped sequences of vocalizations that are characterized by their structural organization and temporal patterns. They are composed of syllables, regularly grouped combinations of sound elements consistently produced together as common units. Song types are unique combinations of different syllables. Males in some territorial songbird species that possess song repertoires (two or more different song types)

can engage in song-type matching, a form of countersinging in which males can match the structural patterns of other males' songs. Although it has been reported in several species, such as song sparrows, great tits, tufted titmouses, western meadowlarks, and cardinals, song-type matching is not universal. There is a considerable number of species that do not song-type match (Catchpole and Slater 2008). Song-type matching requires that neighboring males share at least some song types. In fact, song-type matching has been mainly reported in species with small to moderate song repertoire sizes, containing less than 15 song types. In such species, there is a higher probability that neighbors will share song types. It has been suggested that small repertoires of song types containing simpler songs have a larger role in male-male interactions. While large repertoires of song types with more complex songs functions more in attracting females (Catchpole and Slater 2008).

### The Threat Hypothesis

Krebs et al. (1981) outlined what became known as the *threat hypothesis*. It proposes that song-type matching is a graded signal that communicates agonistic motivation and readiness to escalate aggressive encounters. Krebs et al. (1981) made the prediction that song-type matching should correlate with other intense agonistic behaviors. For example, males should respond faster and approach speakers closer when song-type matched in playback experiments. They also predicted that neighbors should song-type match more often early in the breeding season than later, when territorial boundaries are already established. Furthermore, Beecher et al. (2000) suggested that an additional prediction is implicit in the threat hypothesis. Namely, that males should song-type match neighbors at lower rates when compared to nonneighbors, a form of dear enemy effect.

Subsequent research has provided good support to the idea that song-type matching is a graded signal. Partial song-type matching and repertoire matching (in which males do not song-type match but sing songs that are also in the repertoire of neighbors) induce less aggressive response than whole song matches (Searcy et al. 2008). Studies

in song sparrows (Beecher et al. 2000) have shown that males song-type match neighbors more often early in the breeding season, when territories are not yet established. Playback experiments have also shown that males song-type match neighbors less often than nonneighbors. However, mixed results were found for the prediction that song-type matching should occur along with other intense aggressive behaviors.

### Conclusion

Countersinging is a male-male form of vocal interaction in which songs are used to mediate conflicts over territorial boundaries. It can occur as temporally coordinated singing, in which males can either overlap or alternate between the songs of a counterpart; or as song-type matching, in which structural patterns of songs can be matched. The study of countersinging provides insights into a sophisticated communication system in which different degrees of threat can be embodied, indicating several levels of aggressive intent.

grasp the concept of number and how it is used during enumerative events.

Five criteria have been identified by Gelman and Gallistel (1978) as essential to counting:

1. *The stable order principle* describes the established sequence of verbal or symbolic numbers and their ordinality. To demonstrate the comprehension of this principle, it is necessary for verbal numbers or symbols to be presented in a consistent order (e.g., the second tag applied is always “2” in the Arabic numeral system and is always followed by “3”).
2. *The one-to-one correspondence principle* states that the items in the to-be-counted set and their corresponding counting tags must be paired so that each item receives a maximum of one numerical tag that is completely unique. Specifically, it would be correct to label three items “1-2-3” and incorrect to label the items as “1-1-2.”
3. *The cardinal principle* answers the question of how many things are in a set. It articulates that the final tag used when labeling objects not only represents the ordinality of said objects but also expresses the numerosity of the entire collection. For example, when four objects are labeled 1-2-3-4, the unique tag “4” not only describes the position within the sequence; it also describes the total number of objects in the counted set.
4. *The abstraction principle* illustrates one’s ability to transfer the previously described principles from one to-be-counted set to another. This includes any stimulus set from physical objects, or more abstract and non-visible sets such as sounds. This principle concludes that an individual may count anything, as long as the method of counting remains consistent.
5. *The order-irrelevance principle* recognizes that the order of enumerating items is not important as long as the stable order and one-to-one principles are followed. This means that a line of objects may be counted in any imaginable way (left to right, right to left, the middle out, etc.) and as long as each tag is unique, applied in the proper sequence, and every item receives one tag, the cardinal value will still be exact.

## Counting

## What Is Counting?

Counting is used to specify the absolute number of items in any set, and it is an integral process that we use daily while cooking, playing games and in numerous other ways. In humans, there is evidence that enumerative processes are present even in infancy and eventually develop into formal counting abilities (around the age of 3.5–4 years; Gelman and Gallistel 1978). The ability to count is indicated by one’s capability to fully

A closely related concept is protocounting, and this term is often used to describe the performances of animals such as will be outlined here. This occurs when the most likely process underlying enumerative behavior is counting, although tests have not provided sufficient evidence for a true counting behavior. For instance, a behavior may be labeled as protocounting in circumstances where all counting alternatives have been precluded but control tests (e.g., transfer to demonstrate the abstraction principle) are lacking (Davis and Pérusse 1988).

### What Does Not Count as Counting?

Counting is one specialized mechanism for understanding and representing the absolute numerical value of an enumerated set. However, there are other related forms of numerical and quantitative processes that likely are foundational to the ability to count. These include relative quantity judgments that involve choosing between options on the basis of a “more or less” rule regarding a wide range of magnitudes (e.g., items, volumes, lengths). Sometimes, these choices must be made on the basis of numerosity of sets, and various species can make these relative numerical judgments. In other cases, absolute quantity judgments are made, where the goal is to find a specific quantity (e.g., the circle that is exactly 20 cm in diameter). And absolute numerical judgments can be made by animals, where a specific number of things is the target stimulus (e.g., a sheet of paper with exactly three dots on it). These kinds of tasks are important because they are likely far more accessible to the natural quantitative mechanisms available to other species. In fact, we know that quantity (and even number) is relevant in the judgments made by species ranging from insects (e.g., Dacke and Srinivasan 2008), to fish (Agrillo et al. 2008), to amphibians (Krusche et al. 2010), to birds (Garland et al. 2012), and to many mammals including voles (e.g., Ferkin et al. 2005), marine mammals (e.g., Abramson et al. 2011), bears (Vonk and Beran 2012), elephants (Perdue et al. 2012), coyotes (Baker et al. 2011), and horses (Uller and Lewis 2009). It is these

demonstrations that support the continued possibility that animals may even engage in formal counting, although efforts to this point have offered only tantalizing and suggestive evidence of this rather than clear and definitive cases.

### Controversial History of Counting Research with Animals

The pursuit of counting abilities in animals is one of the most controversial efforts in comparative psychology. This is important to note because that controversy first dampened the continued study of numerical abilities in animals, but after the cognitive revolution, the return to this topic was undertaken with great care. The controversy largely centered on methodological flaws involving poor control over stimulus presentation and unintentional cuing of animals (the “Clever Hans” effect; Beran 2012; Pfungst 1911). Later, it was also suggested that number was a low salience property of stimuli for other species, meaning that number would be used only as a “last resort” by animals engaging in experimental tasks (Davis and Memmott 1982). It was against this backdrop that many of the early studies of relative and absolute numerical judgments were conducted. And it was in pursuit of evidence that number was not a last resort that many of the counting studies were conducted. We now know that animals do use number as a salient property, although often in combination with other properties that tend to covary with number (such as size, density, or amount/volume). The counting studies helped outline this truth.

### Studies of Counting by Animals

With the increased recognition of concerns about cuing, and the refinement of definitions of counting offered by developmental psychologists (e.g., Gelman and Gallistel 1978), new approaches to animal research emerged. And these often produced exciting results and approximated many aspects of the counting principles. These studies have explored varying levels of “counting”

behavior and number sensitivity in diverse species, from large-brained animals to invertebrates. Not surprisingly, a sizeable portion of experiments exploring numerical competence were with great apes, specifically chimpanzees, to determine any capability of such tasks in nonhuman animals (Beran and Rumbaugh 2001; Boysen and Berntson 1989; Boysen et al. 1995; Matsuzawa 1985; Rumbaugh et al. 1989). Other species examined for numerical competence include rats (Davis and Bradford 1986), pigeons (Xia et al. 2000), parrots (Pepperberg 2006), bees (Chittka and Geiger 1995), and ants (Reznikova and Ryabko 2011).

Matsuzawa (1985) reported an impressive performance by a chimpanzee named Ai during a counting task. This chimpanzee had learned to associate symbols with various objects and colors. She also had learned to label sets of items with cardinal labels. When presented with arrays of items of various types, colors, and quantities, she would provide the relevant labels for all properties of that set and often at high levels of correctness. The range of number labeling was small relative to the counting of children over 5 years of age, but still instantiated many of the counting principles outlined above.

An equally impressive series of experiments featured another chimpanzee named Sheba. In an attempt to illustrate one-to-one correspondence, the abstract principle, and both functional and symbolic counting skills of chimpanzees, Boysen and Berntson (1989) trained Sheba to enumerate one, two, or three food pieces and random objects using Arabic numbers. Sheba demonstrated very high accuracy and then transferred her number labels to heterogeneous arrays of items. Testing eventually expanded to include the numerals 0 and 4 as well. When the number 4 was introduced, Sheba's originally high accuracy fell, and she began to use what was deemed a method of motor tagging as she touched and pointed to objects in the array. Following the initial number training procedures, Sheba completed a functional counting task and a symbolic counting task. In these tasks, researchers hid either oranges or the Arabic numbers 0–4 at three different sites around an enclosure. To complete the task, Sheba was required to travel to all three sites and ultimately

select the Arabic number that represented the sum of what she found. In both conditions, Sheba performed well above chance levels. These results suggest that Sheba's numerical skills met many of the criteria necessary to be classified as counting (Boysen and Berntson 1989), at least for small numbers of things.

In another study conducted with Sheba, researchers examined her physical indicating behaviors (i.e., her behaviors of tagging items while interacting with them; Boysen et al. 1995). Sheba correctly labeled sets of eight possible arrays well above chance levels while engaging in these indicating acts, but she tended to over-tag the objects at a near double rate, perhaps arguing against the idea of one-to-one correspondence. However, in some cases, young children also over-tag items when they are learning to count (Gelman and Gallistel 1978). It was possible that the double tags may have actually enhanced Sheba's one-to-one correspondence efforts and aided her in a more accurate count by first partitioning and then tagging each item. Additionally, it is highly probable that these tagging behaviors were a direct result of human interaction in addition to how Sheba was reared and would be highly unlikely to appear spontaneously in a more natural environment (see final section for more comments on this important issue of how to immerse nonhuman animals in environments that might engender counting behavior).

Other work with chimpanzees used computerized testing approaches. In one computerized task, a chimpanzee named Lana was trained to recognize Arabic numbers 1–3 and use a joystick to move a computer cursor to collect the corresponding number of squares on the screen and return the cursor to the Arabic number to conclude the trial (Rumbaugh et al. 1989). During the more challenging trials, where Lana needed to choose three squares, she performed at approximately 80% accuracy. Two chimpanzees (one being Lana and the other her son, Mercury) were tested using similar methods (Beran and Rumbaugh 2001). In that study, the chimpanzees expanded their above-chance performances with the numbers 1–6. However, as the requested number increased in its cardinal value, the

chimpanzees showed a decreasing performance level, reflecting what is called scalar variability. This directly challenged the idea that their performances were reflective of true counting, although it was possible that larger sets also introduced more chances for distraction. In any case, these series of computerized tasks also demonstrated some of the counting principles in the behavior of chimpanzees.

In a long-term study of the parrot Alex, clear evidence emerged of multiple counting principles (see review in Pepperberg 2006). Alex was queried about sets of items, and he had to respond vocally with the correct numeral label for that set. He could do this even when asked about subsets of things in larger arrays (e.g., being asked “How many green block?” when green blocks were mixed in with blocks of other colors and multiple colors of things that were not blocks). Most impressive was his ability to use these numeral labels for highly varied kinds of things, showing evidence of the abstraction principle. And his skills suggested that he understood the ordinal relations of his number labels as well as their cardinal values. However, it was not clear that Alex engaged in tagging of items in any way, making it difficult to demonstrate the one-to-one correspondence principle.

A study by Davis and Bradford (1986) tested rats’ abilities to “count” to the correct reward-baited tunnels while lacking spatial, olfactory, and visual cues so that their choice of the correct tunnel needed to be based exclusively on its ordinal position. To do this, the researchers used a high-walled apparatus so the rats could not rely on visual cues and they baited every tunnel, blocking off the ones that were not in the target ordinal position so as to control for any olfactory cues. Each subject quickly learned to run to its designated target tunnel number, even with varying distance placements of tunnels determined between each trial set. Davis and Bradford suggested that providing a more naturalistic test (of spatial navigation in pursuit of food) allowed the rats to achieve such good performances. Subsequent work using similar methods with rats (e.g., Suzuki and Kobayashi 2000) confirmed sophisticated, number-based responding. However, the rats’ completion of the task was not

to the level of accuracy required of true counting, and they were not able to completely demonstrate all of Gelman and Gallistel’s (1978) principles of counting.

In a task examining constructive counting (symbol converted to numerosity) over responsive counting (numerosity converted to symbol), pigeons were trained on a two-key apparatus to peck the number of times that matched a symbolically displayed number on one key and signal the end of the trial by pecking the remaining key (Xia et al. 2000). Although they performed at above chance levels, accuracy decreased as the required number of pecks increased – another case of scalar variability as seen in some of the work with chimpanzees. Pigeons were also trained to engage in a responsive counting test (Xia et al. 2001) in which a successive symbolic matching-to-sample training process was used to obtain the desired behavior. To correctly complete a trial, pigeons had to match a numerical set of stimuli to the symbol representing that number of things. Although not every pigeon was able to progress through the entire experiment, accuracy for this task was at a more stable level than the previously described study (Xia et al. 2000). This brings to light that skill in responsive counting (or what is sometimes called a “how many” task) may be more easily demonstrated than constructive counting (what is sometimes called a “give me X number” task).

Xia et al. (2001) claimed their study provided evidence of the cardinal principle (in a small range, pigeons can discriminate absolute numbers), the one-to-one correspondence principle (accurately choosing the symbol matching its numerical quantity), the order-irrelevance principle (subjects would vary the order in which they responded to stimuli), and the abstraction principle (novel stimuli were presented by switching counted elements from circles to squares, potentially providing evidence of the ability of transfer). However, despite some compelling evidence of four counting principles, there was no concrete evidence that the subjects had a fixed ordinal sequence in place as required for the stable order principle. And, as noted, evidence of scalar variability challenges the degree to which one can argue that counting is truly occurring.

Another task involved training pigeons to retain the number of flashes presented and produce the correct matching number using pecks (Tan et al. 2007). This experiment had two conditions for stimulus presentation factors that could covary with number, rate-controlled (two, four, or six flashes were presented at a constant rate) and time-controlled (two, four, or six flashes occurred within 10 s). For this task, levels of accuracy for all subjects were fairly low, and this indicated that pigeons were using temporal cues and not fully able to learn rule-based counting strategies. A second experiment attempted to control for this; however, the results proved similar to those of the first experiment of this study. Thus, counting-like performances in pigeons sometimes emerge, but are not always easily obtainable.

In one of the first studies examining counting-like behavior in bees, Chittka and Geiger (1995) trained honeybees to travel to a feeder while passing three landmarks along the way. Testing trials gradually increased and decreased the number of landmarks as well as increased the number of feeders that were to be passed on the way to the original feeder location of the training trials. It was found that during flight, if more landmarks were encountered on the way to the feeder, the bees would land at a shorter distance than in control tests. Furthermore, if fewer landmarks were placed on the way to the original feeder position, bees would end up flying farther. However, many bees did search for the food source at the correct distance, suggesting that the number of landmarks passed was not the sole factor in determining location for honeybees. In another attempt to examine potential counting behaviors in bees, researchers used tunnels with landmarks dispersed throughout (Dacke and Srinivasan 2008). During training, the position of the rewarded landmark varied although its numerical value was held constant. This restricted a bee's ability to learn a specific reward distance, thus discouraging the bees from focusing on travel distance over landmark enumeration. During test trials, the reward location was removed, and bees showed a strong preference for searching the area near the ordinaly consistent landmark to where the reward was previously found. Further experiments

manipulated the landmarks and introduced barriers so that bees were able to view only one landmark at a time. This forced them to see landmarks as sequentially experienced as opposed to simultaneously experienced like in the previous trials. The bees showed an inclination in each of these tasks to fly to their trained landmark number. One interpretation of this experiment was that bees were able to count up to four objects (Dacke and Srinivasan 2008).

In a recent study with honeybees, researchers studied potential symbolic numerical representation (Howard et al. 2019). Two groups of bees were tested. One group was required to match a displayed quantity to a sign representing the numerical value of that quantity, and the other group was to complete the task in the opposite direction. Both groups showed the ability to match appropriately. However, when the same bees were asked to transfer this knowledge by completing the opposite version of the task, both groups were unable to adapt to the new task at a level that was significantly better than chance. Although this was not presented as a test of counting behavior, the results suggest the use of absolute numerosity, and presumably an enumerative process generated the number representations of the quantity stimuli, while the symbols were perhaps organized according to their ordinal and cardinal values.

## Conclusions and Future Directions

Overall, the literature suggests that multiple species have at least some counting-like competencies when it comes to their numerical cognition, including the ability to engage in each of the five counting principles (Boysen and Berntson 1989; Dacke and Srinivasan 2008; Xia et al. 2001). However, many studies did not require individuals to label quantities (Beran and Rumbaugh 2001; Chittka and Geiger 1995; Davis and Bradford 1986; Rumbaugh et al. 1989; Tan et al. 2007). Other studies showed that bidirectional responding was not evident (e.g., Howard et al. 2019). Additionally, the scalar variability effects in relation to accuracy in labeling or constructing numbers of things weaken the

argument that species can grasp numbers higher than about 5 or 6 (e.g., Beran and Rumbaugh 2001). Thus, although there are compelling cases that demonstrate performances that could be very close to counting behavior, it remains uncertain whether other species show the full range of numerical processes and the fully developed sense of number that are required to support counting behavior.

There are three conclusions that one can draw from this literature, each of which lend itself to suggesting that future research should continue on the topic of counting behavior in animals. First, none of the performances of nonhuman species have risen to the counting performances of typically developing children over the age of 6 living in industrialized societies. However, it is important to note that not all human societies have established counting routines (e.g., Gordon 2004). And for those that do not, their performances when asked to count things sometimes look similar to the performances of animals with regard to scalar variability in responding and engagement of an approximate number system rather than a formal counting system. Second, numerous species seemingly grasp and apply some or even all of the counting principles in specific task contexts. This suggests that the foundational cognitive capacities for true counting exist, even if they do not manifest in any known natural behaviors of other species. Third, there are no studies that have provided for animals the kind of immersion in numerical thinking that many children experience (Gelman and Gallistel 1978). Children hear and see counting routines from caregivers in their very earliest experiences. In many societies, even before formal schooling begins, caregivers are modeling and expecting the routines of counting to be used in many social engagements with their children. No studies have immersed apes, dolphins, dogs, or any other species in this type of environment. The projects with Sheba, Ai, and Alex have come the closest, but even those projects did not provide the rich counting experiences that young human children have across many different daily routines. Should such immersion in a counting-rich environment happen, where production of

exact, specific counts is routinely expected (and rewarded) as part of varied daily experiences for animals, we would then better know if the counting principles emerge in a universally applied manner within individuals of a nonhuman species when the environment demands it. They may not, and the “safe money” suggests that they would not. But, it is an important experiment to try.

## Courtship and Mate Choice

Courtship consists of a wide variety of behaviors performed with the intention of achieving an opportunity to mate. Successful courtship results in a pair of animals copulating. Both members of the pair participate in copulation, and this often leads to situations where one individual must persuade the other to choose them as their mate. This process of persuasion occurs through courtship rituals. In some cases, courtship behaviors can be so consistent among members of a species that they are referred to as courtship rituals. These behavioral displays vary across species, but they share the central role of providing a means through which a suitor can advertise their qualities to potential mates. Through performance and evaluation of these displays, individuals engaged in courtship choose their mates; and successful courtship can lead to copulation and the formation of social pair bonds. Pair bonding behaviors and the associated social connection

can thus reinforce a mate choice that began with the performance of courtship behaviors. Individuals often incorporate a combination of bond-forming behaviors and courtship rituals to choose a mate, as social bonds may influence the effectiveness of the courtship ritual.

Courtship rituals can be performed by either males or females. Across species, most rituals involve males performing ornate behaviors to attract the attention of females and court them as potential mates (Darwin 1871). In those cases, the female serves as the evaluator of the quality of a male's displays (Zahavi 1975). Although this can make it appear that females have the sole choice in mate selection, this is not the case, as the initiation of courtship reflects a preference expressed by the male; and mating requires agreement of both participants. Suitors select a recipient of their courtship displays, and receivers evaluate those advertisements and decide whether to accept the suitor's courtship. Therefore, elaborate displays and ritualized behaviors can be important aspects of successful courtship, but they are often only one component in what is ultimately a mutual mate choice.

## Evolution and Importance of Courtship

Sexual reproduction and the variation that it can introduce are key elements in the process of evolution. Sexually reproducing organisms pass their genetic content to the next generation, propagating their species and enabling it to persist through future generations. Sexual reproduction is very common across species. As the saying goes, birds do it, bees do it, and the majority of all eukaryotic organisms engage in sexual reproduction (Goodenough and Heitman 2014). Sexual reproduction is evident in both plants and animals, but courtship rituals are behaviors that are performed across animal species. Therefore, this text will focus on animals in our consideration of courtship behaviors and how they influence reproductive success.

In order for sexual reproduction to occur, each participant must locate and mate with another

member of their species. Factors like opportunity, competition, and attraction can all influence courtship and mating success. It is advantageous for an individual to mate with a partner with high evolutionary fitness, meaning that they are well adapted to survive and produce viable offspring in their environment (Zahavi 1975). It is often said that animals express a "preference" when they choose their mate, but this term can be difficult to define. For example, in most species, individuals do not randomly mate. This has given rise to the idea that certain traits are preferred more than others. Suitors with the preferred trait will leave more offspring, and the numbers of individuals expressing that trait will increase in frequency throughout the population. As Darwin noted in his studies of sexual selection, "when we see many males pursuing the same female, we can hardly believe that the pairing is left to blind chance – that the female exerts no choice, and is not influenced by the gorgeous colors or other ornaments with which the male alone is decorated" (Darwin 1871). This reveals how tempting it can be to think that animals possess a humanlike sense of aesthetics, and the advertisement and appreciation of "beautiful" or "high quality" traits drive courtship and reproduction. The cognitive experiences of animals are the focus of ongoing research, but it remains largely unknown what mental or physiological states occur when an animal encounters a member of its species that expresses some preferred trait. Nonetheless, those traits can be strongly predictive of reproductive success; and that is what is referred to as the traits of the suitors preferred by the receivers of those courtship behaviors.

When one or both members of a pair actively choose a mate from many options, sexual selection occurs. Sexual selection arises from differences in reproductive success that are caused by differences in access to mates (Darwin 1871). Differences in access can occur because of many different factors such as males competing with one another to gain access to mates, or females only granting reproductive opportunities to males that express an abundance of certain preferred traits. Anatomical features such as size,

coloration, and other forms of ornamentation can affect this choice, but behavioral displays can also play a very significant role in affecting which individuals are chosen as mates. The strong link between mate preference and the expression of certain behavioral displays is thought to be a driving force in the emergence of courtship rituals.

Courtship rituals vary greatly depending on the preferred traits which they advertise. Traits can be advertised through many different behaviors including singing, dancing, and demonstrating physical vigor through fighting or other challenging behaviors. Complex rituals can allow for many attributes to be displayed and evaluated at once. Observers can gain insight into the sender's genetic composition, cognitive ability, health, social status, and/or access to specific resources through the quality of a display performed by a potential mate. This gives the observer a great amount of information in a compact and succinct manner. Through displays, the sender attempts to communicate both the quality of their attributes and their availability in order to influence the behavior of the observer. The observer, in turn, analyzes those displays, evaluates their quality, and uses that information as the basis of their decision about whether the sender will be selected as a mate and granted reproductive opportunity.

## Male and Female Roles in Courtship

Courtship rituals occur between two members of the same species and influence the likelihood of mating success (Darwin 1871; Zahavi 1975). Those participants are typically a male and a female, with the male acting as the primary sender of courtship behaviors and the female as the primary receiver, but both parties often make a choice in order for a courtship ritual to be successful (Johnstone et al. 1996). If a potential sender does not judge the potential receiver to be of sufficient quality to be considered as a potential mate, he will not display. If the receiver does not judge the sender and his signal to be of sufficient quality, she will not show preference or grant reproductive access. If both sender and receiver

evaluate the other as high quality, then courtship succeeds, and mating may follow. In that way, mate choice is typically a mutual decision. In the preceding example, the male was portrayed as the sender and the female as the receiver, but there was also a portion of that scenario when the female also performed behaviors to solicit copulation or otherwise indicate her preference for the male. Therefore, both participants acted as sender and receiver at different times in the process, but the male played the role of the sender more than the female.

In the preceding example, both participants made a choice, and those choices were evident in the behaviors expressed by each participant. Therefore, it would be incorrect to say that either participant was the sole sender or receiver or that either was the only one that made a choice. In light of these nuanced contributions by both participants, it can be useful to think of the roles of signaler and receiver as lying along a spectrum between the two sexes (Fig. 1). A specific example of courtship behavior can be characterized by its position along that spectrum as determined by the amount of display or choice made by the male or the female in that example (Fig. 1). Lek mating, where many of a single sex compete or display for members of the opposite sex who are observing them, can be used to illustrate the extremes of the spectrum (*lek* is adapted from the Swedish work *lekställe*, meaning “mating ground”) (Fig. 1).

Male sage grouse provide a classic example of male lekking (left end of the spectrum in Fig. 1). Male sage grouse meet in ancestral areas to lek and strut for females (Wiley 1978). They erect their tail feathers and inflate large, yellow esophageal sacs, which swell and make popping sounds when the air is released, to attract attention (Wiley 1978). They repeat this every morning for weeks, guarding their position in the lek from other males, as central locations offer better mating opportunity (Wiley 1978). At the conclusion of this competition, a small percentage of male sage grouse are selected by the vast majority of females as mates (Wiley 1978). Thus, sage grouse are a classic example of a male lekking system. Lek mating can also occur in the context where females compete to be selected by male observers

(right end of the spectrum in Fig. 1). For example, many species of dancing flies rely on female displaying leks. In these species, females gather in swarms and display, allowing males to observe their behavior and choose their mates from among the group (Funk and Tallamy 2000).

Lek mating systems illustrate the extremes of either male or female choice, but many species do not conform to these extreme examples. Mutual displays, where both sexes participate to a large degree in the courtship ritual, reflect the middle ground (middle of the spectrum in Fig. 1). In these cases, both the male and female serve as signaler and receiver, advertising their own qualities while also evaluating the qualities of their potential mates. Success of the courtship ritual depends on both participants choosing each other. For example, in the pre-copulation displays of red-crowned cranes (middle of the spectrum in Fig. 1), both the male and the female perform an elaborate combination of calls, bill movements, and wing flapping before they copulate (Masatomi and Kitagawa 1975). In this way, both the male and female display to one another, with neither serving as the primary sender or receiver, and both evaluate the quality of their potential mate (Masatomi and Kitagawa 1975). Just as there are differences at

the extremes of the spectrum, there can also be variation within the intermediate portion of that spectrum. In most species, males act as the primary senders, and females act as the primary receivers. There can be exceptions to this trend, such as gray phalaropes and dance flies, in which females act as the primary senders and males act as receivers (Funk and Tallamy 2000; Ridley 1980). These exceptions highlight the fact that courtship rituals are unique to each species. Differences among species can make it challenging to generalize about the nature of courtship rituals, and they make it clear that any study of courtship rituals must include consideration of the context in which they occur.

## Physiological Components of Courtship

Many species have developed physical adaptations that serve in signaling information. These adaptations, called ornaments, come in all sorts of shapes and colors (Darwin 1871; Zahavi 1975). The vibrant plumage of many birds, the colorful abdomen of jumping spiders, the pinnate leg scales of female dance flies, and the crimson combs of male jungle fowl are just a few examples

of ornamentations (Dunn and Cockburn 1999; Frith and Frith 1987; Lenz 1994; Funk and Tallamy 2000; Ligon et al. 1990; Lim and Li 2004; McDonald 1989). In many cases, ornaments reflect both the genetic and nutritional quality of the signaler. High-quality ornamentation requires the associated genes to produce consistent, complex results. Similarly, extreme ornamentation reflects a healthy lifestyle that allows the signaler to expend excess energy and resources to support the development of their ornaments (Zahavi 1975). Thus, genetics define the axis along which the ornament can be developed, but it is experience that determines the degree to which that signal is actually expressed. Fairy-wrens provide a great example of this. The plumage coloration of superb fairy-wrens acts as an honest signal for both the age and nutritional quality of the males displaying those feathers (Dunn and Cockburn 1999). Male superb fairy-wrens molt and grow their new feathers months before the breeding season (Dunn and Cockburn 1999). Older males and nutritionally healthy males molt and begin expressing those colorful feathers much earlier than young or unhealthy males (Dunn and Cockburn 1999). This advantage in timing allows them to begin displaying to females earlier in the breeding season and thus display to females for a longer duration throughout the season, giving them an advantage in terms of claiming territory and attracting mates (Dunn and Cockburn 1999). Thus, the nature of the courtship that females receive is a reflection of the age and nutritional status of the males performing those courtship behaviors.

There are many examples of courtship displays that rely on the receiver's vision to detect information; however, the traits and reproductive status of a potential mate can also be advertised through signals that are detected in other ways. For example, there are nonvisual signals that have profound impact on reproductive behaviors, such as the production of pheromones. Because pheromones are invisible, the importance of these signals for other species can be easily overlooked. Pheromones are small molecules that are produced and released by one individual and are detected by another member of the same species. Like visible

ornaments, the quality of their signals can depend on both genetics and nutritional status. For example, female thynnine wasps are wingless, and they perch on the tips of plants while releasing strong pheromones that attract males (Alcock and Gwynne 1987). Winged males can detect those pheromones in very small concentrations, and they use that information to follow the gradient of increasingly greater concentration until they arrive at their source. Pheromones serve as a signal that guides males to females, and the arrival of the male is often followed by copulation (Alcock and Gwynne 1987). Thus, reproductive signaling can occur through a variety of different behaviors and sensory modalities.

## Behavioral Components of Courtship

Anatomical or physiological ornaments can require many generations to emerge and develop as indicators of an individual's status. Behavior, on the other hand, is much more plastic, allowing behavioral aspects of advertisement and courtship to emerge much more rapidly than structural aspects. Not only are behavioral aspects of courtship very flexible, they are also able to indicate additional aspects of the displayer's status. For example, aspects of cognitive ability and social standing can be displayed through behaviors in ways that may be very difficult or impossible to communicate through physical parameters of ornamentation. This is why behavior is such an important indicator of mate quality, as it reveals characteristics that are acquired within the displayer's lifetime and is thus directly related to that individual rather than an assemblage of individuals across generations. For example, zebra finches sing to attract females. Young males learn their songs from adult male tutors during early development, and the nutrition that the young bird receives during that developmental phase impacts the quality of his song performance then and throughout his life (Brumm et al. 2009). Thus, the quality of a male's song indicates not only his ability to perform that song in the present but also his life history in terms of juvenile nutrition and social environment, as well as his skill in

learning, memorizing, recalling, and rehearsing that song.

Courtship rituals often combine ornamentation and behavior to increase the amount of information signaled to potential mates. For example, intrasexual fighting is common in courtship rituals. These agonistic behaviors use direct competition to indicate the strength and health of the fighters. While the structures used to fight are often anatomically determined, animals must be healthy, reflecting good nutrition; skillful, reflecting good cognition; and strong, reflecting good genetics, in order to win the fight. While these behaviors often do not directly lead to mating, they are correlated with mating success, as victors are more likely to gain an opportunity to mate. Thus, fighting behavior can communicate information about multiple attributes, including physiological traits that an observer would not be able to detect directly. In jungle fowl, male fighting success is correlated with the amount of testosterone the male produces (Ligon et al. 1990). Other testosterone-dependent traits, like comb color and size, are evaluated by females of other species and are also important for mating success (Ligon et al. 1990). This correlation between a physiological trait and mating success is thought to emerge because males with more testosterone are able to fight competitors and court females with higher rates of success (Ligon et al. 1990).

Another form of physical courtship ritual common across the animal kingdom is dancing, in which rhythmic movements of the body are used as a signal. Dancing allows the signaler to display their physical prowess to the evaluator. Ornaments are often displayed during these courtship rituals, signaling additional attributes. Jumping spiders, for example, dance to attract females. When attempting to court, the male raises his body and flexes his vibrant abdomen while arching his legs and vibrating his palps (Lim and Li 2004). He then will skitter toward the female and tap her legs to solicit copulation (Lim and Li 2004). Male superb birds-of-paradise are famous for their elaborate, multi-step displays. The first step involves a male sleeking his plumage while crouching to attract females to his area, bowing

and displaying his unerect cape to any nearby individuals (Frith and Frith 1987). After a female lands on his perch, the male spreads his tufts and cape, creating a black oval and thrusting his brightly colored breast shield forward (Frith and Frith 1987). Iridescent pseudo-eyes above his real eyes and clicking sounds made by wing movements accompany the male as he dances near the female by hopping around her, calling, or displaying his bright yellow mouth coloration (Frith and Frith 1987). If the female finds the dance attractive, the two will copulate (Frith and Frith 1987). This dance requires strong males with healthy genetic backgrounds and nutritional experience to produce these vigorous dances and vivid ornaments.

Many animals use auditory stimuli to signal information, but none are as famous for the Passerine songbirds. Songbirds sing to communicate. Their songs, unlike anatomical ornaments, must be learned and practiced. Males learn their songs during juvenile development by copying song elements performed by adult tutors, and they rely on hearing throughout their life to practice and maintain the quality of those songs. In this way, a male's song, like that of the male zebra finch, provides insight into not only the present health of the bird but also that male's ability to learn and perhaps other aspects of his cognitive ability (Boogert et al. 2011; DuBois et al. 2018; Sewall et al. 2013). Developmental stress, poor health, and many other factors can negatively impact the male's song quality, making it an important signal for use in female evaluation of the singer as a potential mate (Brumm et al. 2009).

Courtship rituals can also incorporate features of the environment to reveal the signaler's resourcefulness and skill. For example, displayers can advertise their ability to claim and defend territory, as well as their ability to provide resources. A common form of these rituals involves nest building. Male pufferfish construct complex sand circles, ridged with sand ripples, decorated with shells, and built using small, soft sand particles (Kawase et al. 2013). These nests take days for the male to form and refine, showing the quality of the male's territory and his skill in building a shelter to provide for potential

offspring (Kawase et al. 2013). Bowerbirds, however, are possibly the most famous nest builders. Regent bowerbirds build elaborate bowers, consisting of raised walls made of sticks that come together to form a tunnel-like structure, and the males decorate those structures with objects they find (Lenz 1994). These are often very colorful objects, such as snail shells, bright leaves, and pieces of blue plastic; and the decorations are presented to females as part of the courtship ritual (Lenz 1994). Female bowerbirds visit males with quality bowers for longer periods of time, reflecting the female's preference (Lenz 1994). Other species also incorporate found objects into their courtship rituals, such as gifts of food presented by male dancing flies to females immediately prior to copulation (Funk and Tallamy 2000). These gifts are so nutritional that females in some species of dancing flies have lost the ability to hunt and are thought to depend on these nuptial gifts (Funk and Tallamy 2000).

In addition to forms of courtship in which a specific behavior serves as the primary means of display, many forms of courtship ritual consist of a combination of displays. For example, brown-headed cowbird males sing while puffing their chests and flapping their wings to attract females (Cooper and Goller 2004). This "song and dance" exertion often causes pauses in their song (Cooper and Goller 2004). Males of higher physical capability can continue with fewer pauses, and this is thought to indicate that they have the motor and respiratory capacity to handle the exertion. (Cooper and Goller 2004). Long-tailed manakins also offer a great example of complex multimodal mating rituals. These vibrant, lekking birds work in teams to attract females (McDonald 1989). One high-ranking (alpha) male and another subordinate (beta) male first attract females with a chorus of calls (McDonald 1989). Once the female has been drawn into the area and can observe their behavior, they engage in a series of backward jumps over each other while singing and fluttering in the air (McDonald 1989). If the female is receptive, the alpha may solo display then copulate (McDonald 1989). This combination of synchronized singing and dancing is especially unusual among mating rituals, as multiple males work

together to display; but only one gets an opportunity to mate (McDonald 1989). The alpha male signals his health and genetics through his bright plumage, consistent calls, and dance, while he also displays his social status in his duet and synchronized dancing (McDonald 1989). The beta, in turn learns and practices the proper method of singing and dancing and can eventually become an alpha when he is older and more skilled (McDonald 1989).

Behaviors that comprise courtship rituals can also have an impact beyond direct courtship. For example, courtship rituals can help form and maintain social bonds between two individuals. Gray phalaropes use many aspects of their courtship behaviors to bond with a male days before copulation occurs (Ridley 1980). Black swans perform the triumph dance whenever one of the pair chases out an intruder, and this behavior increases their pair bond even though it is not always followed by copulation (Kraaijeveld et al. 2004). Alpha and beta male long-tailed manakins likewise form a complex social bond through displaying together (McDonald 1989). Finally, these displays can also advertise the signaler's quality to potential competitors. In highly competitive courtship rituals, like leks, high-quality displayers dissuade competitors and take optimal positions through the use of their displays (Wiley 1978; Jukema and Piersma 2006).

## Dishonesty in Courtship Rituals

The preceding examples illustrate that courtship signals can have a number of benefits for the sender. In many cases, they are also informative and thus beneficial for the receiver. However, not all advertisements are honest signals of the sender's traits. Most courtship behaviors are reliable indicators of the quality of the associated sender. These are called "honest" signals, and they enable the receiver to form an accurate assessment of the sender's quality. Displayers of certain species, however, have developed methods of using dishonest signaling to mate with evaluators. For example, male cuttlefish can change their color and shape. Males typically

display bright patterns to females in order to court them and then guard their mates from rival males (Norman et al. 1999). Small males, however, cannot compete with larger males. Small males sometimes use deceptive signaling to copulate with females. In these cases, a small male mimics the mottled appearance of a female. He uses this deception to enter the territory of a male that would otherwise chase him off (Norman et al. 1999). The deceptive male can then attempt copulation with the guarded female when the large male is distracted (Norman et al. 1999). Male mourning cuttlefish take deception one step further. A male of this species can display male courtship markings to a female on one side of his body while simultaneously displaying female markings to a rival, territorial male on his other side (Brown et al. 2012). In this way, deceptive males can court protected females while avoiding retribution (Brown et al. 2012).

One of the most impressive examples of deceptive rituals lies with the shorebirds called ruffs. Ruffs typically protect small territories, and males engage in lekking to attract females (Jukema and Piersma 2006). What makes them so interesting is that the males come in three polymorphs, each one genetically tied to a different courtship ritual (Jukema and Piersma 2006). Independent males are large and brown, displaying their plumage to potential mates and chasing away other independent males (Jukema and Piersma 2006). Satellite males are smaller, white, and unthreatening (Jukema and Piersma 2006). Independent males tolerate satellite males in their territory, giving them the opportunity to quickly attempt copulations with the females also in the territory (Jukema and Piersma 2006). The final form of male ruffs are referred to as faeders, the smallest and most drab of the three (Jukema and Piersma 2006). Faeders mirror the plumage color and size of female ruffs and can freely move between independent males' territories (Jukema and Piersma 2006). In this way, they can attempt to sneak copulations from resident females (Jukema and Piersma 2006). In these examples, dishonest signaling is used to gain access to previously inaccessible females. While these behaviors are quite different than honest displays, their performers are

nonetheless able to use their ornamentation and behaviors to mate with females, revealing them as unusual and fascinating forms of courtship rituals.

## Summary

Reproduction is one of the most important processes for animals, providing a mechanism to populate future generations and propagate species. Sexual selection results from individuals choosing mates based on the quality of certain preferred traits that are thought to provide benefits for either them, their offspring, or both. In order to advertise their traits and assess the quality of potential mates, many species have developed ornamentation and behaviors that serve as indicators of those traits. These are used in courtship rituals to attract mates, as well as serving other uses like defending territories and strengthening social bonds. Complex courtship rituals allow for more information to be signaled, and aspects of an individual's status such as health, genetic background, life experience, and social ranking can be communicated through courtship rituals. These accurate indicators of an individual's traits are called "honest" signals. Most courtship behaviors consist of honest signaling, but the presence of "dishonest" signals in some species reveal that not all courtship rituals are meant to signal quality. These deceptive signals are the exceptions, because they can only remain successful while honest signaling is the norm. Whether it be through bright coloration, fighting, singing, dancing, gift giving, or any combination of physical attributes and behaviors, the ability to copulate with the opposite sex is vital for the survival of a species. The goal of identifying and courting a quality mate has led animals to develop the many wondrous and complex courtship rituals found in nature today.

## Introduction

The skull forms a part of the axial skeleton which comprises of 28 bones, most of which are paired (11 paired and 6 unpaired bones). Out of these 21 bones are firmly connected to one another by means of sutures and synchondrosis which renders them immovable. The main functions of the skull are to protect the brain, its coverings and to help in communicating one's feelings via numerous facial expressions. These functions can be attributed to the two parts of skull (Retzlaff 1987):

1. Neuro-cranium
2. Splanchno-cranium

### Neuro-cranium

This includes eight bones, namely, frontal, ethmoid, sphenoid, occipital, temporal and parietal (the latter two are paired). These bones are

involved in enclosing the cranial cavity to house the brain and its meninges, subsequently providing protection to the structures without hindering the blood circulation. The neuro-cranial vault is called as calvaria and is composed of membranous or dermal bones, whereas the bones forming the cranial base are ossified in cartilage.

### Splanchno-cranium

This part of the skull forms the facial skeleton which has cavities (nasal, orbital), alveolar processes in upper and lower jaw to accommodate the teeth and bony palate. The splanchno-cranium provides attachments to the facial muscles which control the movements of the oral fissures, palpebral fissures, and anterior nasal apertures indirectly providing different facial expression. Structurally, 14 bones (unpaired mandible and vomer; paired nasal, maxilla, palatine, lacrimal, zygomatic, and inferior nasal concha) are involved in the formation of facial skeleton which are originating from the pharyngeal arches.

The part of skull this chapter focuses on is the cranial base which is a part of the neuro-cranium and is composed of 5 bones of the skull, namely, ethmoid, sphenoid, occipital, both frontal and both temporal. The term cranial base had

its origin from Latin term *basis cranii* and it forms the floor of the skull.

To complete the study of cranial base, it requires inspection from inside (termed as **norma internalis**) and outside (termed as **norma basalis**). Both the normas are divided into 3 subparts each as shown in Fig. 1. in order to make the topic easy to understand.

### Norma Basalis

The view of skull base from outside the cranium is referred to as norma basalis. For the ease of explanation, norma basalis is divided into 3 subparts, as shown in Fig. 1.

Each subpart comprises of various components, which are grouped as:

1. Bony components
2. Sutures between bony components
3. Muscular or ligamentous attachments
4. Special/characteristic features – fossa/foramen/processes/tubercle, etc.

The **anterior part of norma basalis** (Fig. 2) extends from the anterior margin of alveolar arch of maxilla to the posterior limit of the hard palate.

**Cranial Base, Fig. 1** Parts of the cranial base

**Cranial Base, Fig. 2** Features of anterior part of norma basalis

Bony components of two subdivisions are palatine process of maxilla and horizontal parts of palatine bones for the bony palate and the second subdivision comprises of the alveolar arch of maxilla. The suture present between these bony components is called as **cruciform suture**, which is formed between palatine process of maxilla and horizontal parts of palatine bones. The special features in this part comprise of **incisive fossa**, present behind central incisor tooth affecting inter-maxillary suture, and communicates with the nasal cavity **transmitting** long naso-palatine nerve from above and branches of greater palatine vessels from below. **Greater palatine foramen** can be seen as single foramen medial to 3rd molar tooth on either side **transmitting** greater palatine vessels and nerves, and **lesser palatine foramen** are paired foramina on each side posterior to greater palatine foramen and **transmit** lesser palatine vessels and nerves. A backward projection

in the mid-sagittal plane called as posterior nasal spine gives attachment to musculus uvulae, a part of soft palate. The free margin of the palatine bone gives **insertion** to tensor veli palatini in the form of palatine aponeurosis (Datta 2009).

The **intermediate part of norma basalis** (Fig. 3) extends from the posterior limit of anterior part to transverse line across the anterior margin of foramen magnum. **Bony components** of the median part comprise of posterior border of the vomer, inferior surface of the body of sphenoid bone, and basilar part of occipital bone. Whereas the bony architecture of the para-median part has medial and lateral pterygoid plates of sphenoid bone, infratemporal surface of greater wing of sphenoid bone and temporal bone's squamous, tympanic and petrous part. On either side **squamo-tympanic fissure** is present which is divided into anterior petro-squamous fissure and posterior petro-tympanic fissure by tegmen

**Cranial Base, Fig. 3** Features of middle part of norma basalis

tympani of petrous part of temporal bone. The **muscular/ligamentous attachments** on different bony components of the intermediate part are: the **basilar part of occipital bone** gives postero-anterior attachments to pharyngo-basilar fascia, bucco-pharyngeal fascia, prevertebral fascia, and pharyngeal raphe at pharyngeal tubercle, while it also provides **insertion** to longus capitis and rectus capitis anterior muscles. The posterior border of **medial pterygoid plate** is free and has **scaphoid fossa** (or Cruveilhier's fossa) which gives origin to tensor veli palatine and also has a hook like projection called as **hamulus** which gives support for medial turning of tensor veli palatine, enabling it to enter soft palate (Standring 2016). Hamulus is connected to mandible via pterygo-mandibular raphe behind 3rd molar tooth. The **lateral pterygoid plate** gives **origin** to medial pterygoid muscle from its medial surface and lateral head of lateral pterygoid muscle from its lateral surface. The space between the lateral and medial pterygoid process is known as **pterygoid fossa**. The **infra-temporal surface of greater wing of sphenoid** forms the roof of infra-temporal fossa which is limited by the

infra-temporal crest, which gives **origin** to upper head of lateral pterygoid muscle. The **spine of sphenoid bone** gives attachments to 2 muscles and 3 ligaments, namely, tensor veli palatini and tensor tympani muscles, while the ligaments are anterior ligament of malleus passing through the petro-tympanic fissure, speno-mandibular ligament, and pterygo-spinous ligament. The lateral-most bony component of intermediate part of norma basalis is the petrous part of temporal bone which gives **origin** to levator veli palatini from its apex. The **characteristic features** are **pharyngeal tubercle** on the basilar part of occipital bone which gives attachment to pharyngeal raphe on which pharyngeal constrictors are inserted, **processus tubarius** on the midpoint of posterior free border medial pterygoid plate (Thomson 1914). The **palate-vaginal canal** (or pharyngeal canal) is placed between the sphenoid bone and the palatine bone connecting the nasopharynx with the pterygopalatine fossa. An inconstant **vomero-vaginal canal** (no structure passes through it) may lie between the ala of the vomer and the vaginal process of the sphenoid bone, medial to the palatovaginal canal,

and lead into the anterior end of the palatovaginal canal. The palatovaginal canal **transmits** the pharyngeal branch of the third part of the maxillary artery and pharyngeal nerve from the pterygopalatine ganglion. The infra-temporal surface of greater wing of sphenoid is characterized by presence of **sulcus tubae**, formed between postero-medial border of greater wing of sphenoid and petrous bone for lodging cartilaginous part of auditory tube, and also by the presence of major foramina of skull such as **foramen ovale** which transmits (M. A. L. E)\* two roots of **mandibular nerve** (motor and sensory), **accessory meningeal artery**, **lesser petrosal nerve**, **emissary vein** to connect cavernous sinus with pterygoid venous plexus; **foramen spinosum** transmits nervous spinosus from mandibular nerve trunk [branch of trigeminal nerve, cranial nerve V (C. N. V)] and middle meningeal artery branch of first part of maxillary artery, posterior to the foramen spinosum lies spine of sphenoid. In between the sphenoid, apex of petrous temporal and basilar

part of occipital bone lies a triangular hole in the base of skull called as **foramen lacerum** (Latin for lacerated piercing) which is filled with cartilage after birth and so mostly nothing is transmitted through it. Internal carotid artery enters the cranial cavity through carotid canal opening present on the inferior surface of petrous part of temporal bone (Datta 2009).

The **terminal/posterior part** (Fig. 4) of norma basalis extends from posterior limit of its intermediate part, i.e., posterior to the transverse line across the anterior margin of foramen magnum. The remaining two parts of the occipital bone, i.e., the condylar (comprising of the condyles, jugular process and jugular tubercle) and the squamous parts, constitutes the **bony components** of the median subdivision, while the para-median one is formed by remaining part of inferior surface of petrous temporal and mastoid and styloid processes of the temporal bone. The **sutural components** present in this part of norma are **occipito-mastoid suture**, which continues with

**Cranial Base, Fig. 4** Features of posterior part of norma basalis

the lambdoid suture between occipital and parietal bones, and **petro-occipital suture**. The **attachments** found on the terminal part in antero-posterior direction are: **alar ligament** from dens of axis gets attached on the tubercle of occipital condyle, dividing the foramen magnum into small anterior and large posterior compartments. The styloid process gives attachment to 3 muscles (nerve supply) and 2 ligaments, thus converting into **styloid apparatus** (Datta 2009). The attachments of styloid process are styloglossus muscle (C. N. XII), stylohyoid muscle (C. N. VII), stylopharyngeus muscle (C. N. IX), and stylohyoid and stylomandibular ligaments. On the squamous part, an external occipital protuberance is seen from which appears **highest and superior nuchal lines** on both sides whereas an external occipital crest extends up till the mid-sagittal point on the posterior margin of foramen magnum called as **opisthion** (Jha et al. 2008). From the midpoint of external occipital crest, **inferior nuchal line** extends on either side of the cranial base. The external occipital crest gives attachment to **ligamentum nuchae**. The lateral one-third part of superior nuchal line gives **insertion** to sternocleidomastoid muscle, while the medial two-third part gives **origin** to trapezius muscle. Beneath the sternocleidomastoid muscle, **insertion** of splenius capitis and longus capitis can be seen on the mastoid. The area between superior and inferior nuchal line is occupied by the **insertion** of semispinalis capitis, whereas the area below the inferior nuchal line is occupied by insertion of rectus capitis posterior major, minor, and

obliquus capitis superior medio-laterally. The features that **characterize** this part of norma basalis are: in the **median part** are foramen magnum, external occipital crest, and external occipital protuberance (highest point is called as inion). **Foramen magnum** is a large oval aperture of the occipital bone for communication between posterior cranial fossa and vertebral canal. The midpoint of anterior margin of foramen is termed as basion. It is divided by alar ligament of dens into anterior small osseo-ligamentous compartment (transmitting apical ligament of dens, upper band of cruciate ligament, and membrane tectoria) and posterior large neuro-vascular compartment (transmitting medulla oblongata and meninges, fourth part of vertebral arteries, spinal root of accessory nerves, anterior and posterior spinal arteries, and part of tonsil of cerebellum). The features of **para-median part superior nuchal line, inferior nuchal line, hypoglossal canal** transmitting hypoglossal nerve (C. N. XII), **condylar fossa** with posterior condylar foramen transmitting emissary vein to connect sigmoid sinus with suboccipital venous plexus, **jugular foramen** (Fig. 5) transmitting glossopharyngeal nerve (C. N. IX), vagus nerve (C. N. X), accessory nerve (C. N. XI), and internal jugular vein, **mastoid canaliculi** in the lateral part of the jugular fossa (Fig. 6) for the entrance of the auricular branch of the vagus nerve, **styloid process** – 2.5 cm long projection developing from cartilaginous part of 2nd branchial arch, **stylo-mastoid foramen** transmitting facial nerve (C. N. VII) and provides entrance to stylomastoid branch of posterior auricular artery, in the bony

**Cranial Base, Fig. 5** Structures passing through Jugular foramen

**Cranial Base, Fig. 6** Relations of Jugular fossa

ridge dividing the carotid canal from the jugular fossa is the small inferior **tympanic canaliculus** for the passage of the tympanic branch of the glossopharyngeal nerve (Gleeson 2016).

## Norma Internalis

The view of skull base from inside the cranium is referred to as norma internalis and is divided into 3 cranial fossas, as presented in Fig. 1.

Each cranial fossa has various components to be learned of, which are grouped as:

1. Bony components
2. Special features – fossa/foramen/processes/tubercle/grooves, etc.

The **anterior cranial fossa extends** (Fig. 7) from the inner surface of frontal bone's inner table to the posterior border (also called as sphenoidal crest) of lesser wing of sphenoid on each side and anterior border of sulcus chiasmaticus in median region. Three **bones** are involved in its formation, namely, cribriform plate of ethmoid bone, orbital plates of the frontal (has impressions of sulci and gyri from the inferior surface of frontal lobe of brain), and lesser wings with jugum sphenoidale of the sphenoid bone. The anterior cranial fossa has six **special features**, (1) **cribriform plate**:

it forms the roof of nasal cavity and has numerous small apertures for passage of olfactory nerves (C. N. I) from nasal mucosa to olfactory bulb overlying the plate; (2) **ethmoidal foramina**: on both sides of cribriform plate 2 foramina can be seen, called as anterior and posterior ethmoidal foramina. The anterior ethmoidal foramen transmits anterior ethmoidal nerve, continuation of nasociliary nerve, and anterior ethmoidal artery, a branch of ophthalmic artery. The posterior ethmoidal foramen transmits posterior ethmoidal nerve, a branch of nasociliary nerve and posterior ethmoidal artery, a branch of ophthalmic artery; (3) **crista galli** (Latin for crest of the rooster), a triangular process projecting upward from cribriform plate and gives attachment to falx cerebri, a modification of dura mater; (4) **foramen caecum**, it intervenes between crista galli and frontal crest and rarely transmits vein from nasal mucosa to superior sagittal sinus; (5) **jugum sphenoidale**, a part of lesser wing of the sphenoid which articulates with ethmoid and forms the roof of sphenoidale air sinus; and (6) **anterior clinoid process**, bony projections at the medial end of posterior margin of lesser wing of sphenoid, gives attachment to anterior end of free margin of tentorium cerebelli (Koshi 2018).

The **medial cranial fossa** (Fig. 8) is butterfly shaped and **extends** from the posterior border of

**Cranial Base, Fig. 7** Features of anterior cranial fossa

lesser wing of sphenoid to the upper border of petrous temporal on each side and dorsum sellae of sphenoid bone in median region. It is further divided into median and lateral subdivisions. The median part comprises of body of sphenoid presenting sulcus chiasmaticus in front, sella turcica behind, and carotid groove on either side, while the lateral part is formed by cranial surface of greater wing of sphenoid bone and inner surface of squamous part and anterior surface of petrous part of temporal bone (Sinnatamby 2011). The **special features** of the median subdivision of middle cranial fossa are sulcus chiasmaticus and sella turcica. **Sulcus chiasmaticus** is a transverse groove which leads to optic canal on each side which transmits optic nerve and ophthalmic artery. The sulcus is housing the optic chiasma, which lies slightly above it. **Sella turcica** (latin for Turkish seat) comprises of: (a) tuberculum sellae, the posterior limit of sulcus chiasmaticus

giving attachment to diaphragm sellae forming roof of hypophyseal fossa; (b) middle clinoid process, a small projection on each side of tuberculum sellae which gets connected to anterior clinoid process via carotico-clinoid ligament thus forming carotico-clinoid foramen transmitting upturned internal carotid artery. At times, ossification of the carotico-clinoid ligament occurs which can lead to compression of internal carotid artery (Özdoğan et al. 2003); (c) hypophyseal fossa, a depression containing pituitary gland, with seldom presence of cranio-pharyngeal canal (marks the original position of Rathke's pouch); (d) dorsum sellae, bony plate presenting *posterior clinoid process* on each end, which gives attachment to tentorium cerebelli. Apart from these bony features, some ligamentous features are also seen in the middle cranial fossa, these are *Oculomotor trigone*, formed by crossing margins of free and attached

**Cranial Base, Fig. 8** Features of middle cranial fossa

tentorium cerebelli on either side of the posterior clinoid process and is pierced by oculomotor (C. N. III) and trochlear nerves (C. N. IV). An osseo-ligamentous foramen called as **Dorello's canal** opening is formed by **petro-sphenoid ligament** (or **Gruber's ligament**) which connects petrosal process on the lateral margin of dorsum sellae and tip of petrous temporal, through this canal abducent nerve (C. N. VI) passes and appears in cavernous sinus (Ambekar et al. 2012). On each side of sella turcica, an italic “f” shaped **carotid groove** is seen housing internal carotid artery with plexus of sympathetic nerves around it. On the lateral subdivision of the middle cranial fossa, features can be studied with respect of parts of the bony components forming the subdivision. The cranial surface of greater wing of sphenoid presents with, (a) **superior orbital fissure** (Fig. 9), a slit enclosed between lesser wing, greater wing and body of sphenoid bone, acting as a passage between orbit and middle cranial fossa; (b) foramen rotundum, transmitting maxillary division of trigeminal nerve from trigeminal ganglion in middle cranial fossa to pterygopalatine fossa; (c) foramen ovale (see

section “**Norma Basalis**”); (d) foramen spinosum (see section “**Norma Basalis**”). The inner surface of squamous part of temporal bone presents grooves for middle meningeal vessels. The anterior surface of petrous temporal bone presents with three important features, (1) **trigeminal impression**, a fossa at the petrous apex which lodges trigeminal ganglion in dural pouch called as **cavum trigeminale**; (2) **arcuate eminence**, an elevation behind trigeminal impression overlying anterior semi-circular canal of internal ear; (3) **tegmen tympani**, a thin bony plate covering the anterior petrous surface and forming common roof of mastoid antrum, tympanic cavity, and bony part of auditory tube. It presents 2 foramina, **lateral** and **medial**. The lateral foramina transmit **lesser petrosal nerve (branch of C. N. IX)** and medial foramina transmit **greater petrosal nerve (branch of C. N. VII)**. It also divides squamotympanic fissure into 2 parts, petro-squamous anteriorly and petro-tympanic posteriorly (see section “**Norma Basalis**”). The foramen lacerum (see section “**Norma Basalis**”) can be visualized as a feature of this cranial fossa (Basmajian and Slonecker 1989).

**Cranial Base, Fig. 9** Structures passing through Superior orbital fissure

On the inferior aspect of the middle cranial fossa (externally) there are important fossas or spaces which are being mentioned in Table 1, along with the structures forming the boundaries of them and their contents (Whitefield 2016).

The **posterior cranial fossa** (Fig. 10) can be observed till up to **internal occipital protuberance** and groove for transverse sinus. It can also be divided into median and lateral or para-median subdivisions. The bony components of median subdivision are squamous and basilar part of occipital bone as well as the posterior surface of the body of sphenoid bone. The para-median subdivision comprises of posterior surface of petrous part of temporal bone and postero-inferior angles of the parietal bone. **Features** of the median part comprise of **foramen magnum** (see section “**Norma Basalis**”). Anterior to foramen magnum, a sloping surface of bone known as **clivus** is formed by fusion of basi-occiput and body of sphenoid [a primary cartilaginous joint between basi-occiput and body of sphenoid (synchondrosis) which gets replaced by bone (synostosis) at around 25 years of age] and is related to pons, medulla oblongata, separated by basilar artery and basilar venous plexus. Posterior to foramen magnum, the inner surface of occipital

bone presents **internal occipital crest**, which extends upwards to internal occipital protuberance and divides near the posterior margin of foramen magnum forming triangular fossa called as the **vermian fossa**, housing inferior vermis of cerebellum. A transverse sulcus (housing transverse sinus) extends from either side of internal occipital protuberance and continues into sigmoid sulcus (housing sigmoid sinus) involving postero-inferior angle of parietal, mastoid part of temporal, and upper surface of jugular process of occipital bone. In the para-median part, special features are seen on either side of foramen magnum. The notable features are hypoglossal canal (see section “**Norma Basalis**”) and jugular foramen (see section “**Norma Basalis**”). The three borders of petrous temporal bone are associated with venous sinuses, superior border with superior petrosal sinus, posterior border with sigmoid sinus, and antero-inferior border with inferior petrosal sinus. The posterior surface of petrous temporal bone presents with (a) **internal acoustic meatus**, 1 cm in length, it transmits facial (C. N. VII) and vestibule-cochlear (C. N. VIII) nerves and labyrinthine artery branch of anterior inferior cerebellar artery (85–100%) or basilar artery (<15%); (b) **subarcuate fossa**, a depression situated behind and lateral to internal meatus

**Cranial Base, Table 1** Anatomical spaces that lie inferior to the middle cranial fossa

| Space                                              | Principal relations (boundaries)                              | Major contents                                                  |
|----------------------------------------------------|---------------------------------------------------------------|-----------------------------------------------------------------|
| Infratemporal fossa                                | M – lateral pterygoid plate                                   | Mandibular division of trigeminal nerve                         |
|                                                    | L – ramus of mandible                                         | Otic ganglion                                                   |
|                                                    | A – posterior surface of maxilla                              | Chorda tympani nerve                                            |
|                                                    | P – styloid process                                           | Medial and lateral pterygoid muscles                            |
|                                                    | S – greater wing of sphenoid                                  | Maxillary artery and vein                                       |
|                                                    | I – opens into neck                                           | Pterygoid venous plexus                                         |
| Pterygopalatine fossa                              | M – palatine bone and nasal cavity                            | Maxillary nerve from foramen rotundum                           |
|                                                    | L – infratemporal fossa via pterygomaxillary fissure          | Nerve of pterygoid canal (Vidian nerve)                         |
|                                                    | A – maxilla                                                   | Pterygopalatine ganglion                                        |
|                                                    | P – pterygoid process of sphenoid                             | Pterygopalatine ganglion                                        |
|                                                    | S – body of sphenoid                                          |                                                                 |
|                                                    | I – pterygoid plates                                          |                                                                 |
| Parapharyngeal space (anterior to styloid process) | M – pharynx                                                   | Eustachian tube                                                 |
|                                                    | L – medial pterygoid and parotid fascia                       | Tensor and veli palatine muscles                                |
|                                                    | A – fascia covering medial pterygoid and tensor veli palatini | Ascending pharyngeal and facial arteries                        |
|                                                    | P – styloid muscles and fascia                                | Branches of the glossopharyngeal nerve (to pharynx)             |
|                                                    | S – sphenoid bone                                             |                                                                 |
|                                                    | I – hyoid bone                                                | Fat                                                             |
| Infrapetrosal space (posterior to styloid process) | M – posterior pharynx                                         | Jugular bulb                                                    |
|                                                    | L – mastoid process                                           | Internal carotid artery                                         |

and is prominent in new born; (c) **aqueduct of vestibule**, a bony canal behind the internal meatus lodging saccus and ductus endolymphaticus; (d) **pyramidal notch**, present at the lower border of petrous temporal bone, just above the jugular foramen and lodges inferior ganglion of glossopharyngeal nerve (Basmajian and Slonecker 1989).

## Applied Anatomy

The base of skull is fractured mainly in accidents. Depending on the direction of force transmitted, the fractures of the base of the skull can be of

three types: (1) **Longitudinal fracture**, which divides the base into two halves. This can be seen in cases of run over by a vehicle where the impact can be on the face and forehead or on the back of the head or from front-to-back or back-to-front compression of the head. (2) **Transverse fracture** (Fig. 11a), where the base is divided into two parts, front and back half. This type of fracture results from an impact on either side of the head or side-to-side compression of the head as when run over by a vehicle or hit with heavy and sturdy object like baseball bat. In cases where the fracture line runs from side to side across the middle cranial cavities separating the base into two halves, anterior and

**Cranial Base, Fig. 10** Features of posterior cranial fossa

**Cranial Base, Fig. 11** (a) Dashed line depicting margins of transverse/hinge fracture. (b) Dashed line depicting margins of ring fracture

posterior, are termed as **hinge fracture**. As they are seen in majority of motorcycle accidents, they are also known as **motorcyclist's fracture** (Reddy and Murty 2014). (3) **Ring fractures** (Fig. 11b), which occurs in the posterior cranial fossa around the foramen magnum and is commonly caused by a fall from a height onto the feet. The potential energy acquired from the height of the fall if not absorbed by fractures of the legs, pelvis, or spine is then transmitted up the cervical spine. This puts pressure on the skull and causes the fracture of the occipital bone in a circular fashion around the foramen magnum and hence giving the term **foramen fracture**. In this case there occurs no injury to scalp or blood infiltration (Buris 1993).

In fracture of base of skull, cranial nerve damage is commonly seen. Fracture of anterior cranial fossa is usually due to direct impact or a heavy blow on the chin and involves escape of blood or CSF or both from nose. The middle cranial fossa fractures are seen due to direct impact behind the ear causing fracture of the petrous temporal bone and thus involving the middle ear, which allows blood and CSF to escape from the ear. The posterior cranial fossa fracture usually occurs from direct impact on the back of the head. Here, extravasation of blood is seen behind the mastoid process or the blood may escape into the nape of the neck deep to the postvertebral muscles. If the fracture disrupts foramen magnum, cerebellar contusions may result leading to hernia of cerebellar tonsils due to edema (Wineski 2019).

## Creatinine

Karthikeyan Pethusamy<sup>1</sup>, Ankita Raj<sup>2</sup> and Sajib Kumar Sarkar<sup>3</sup>

<sup>1</sup>Department of Biochemistry, All India Institute of Medical Sciences (AIIMS), New Delhi, India

<sup>2</sup>Vardhman Mahavir Medical College, New Delhi, India

<sup>3</sup>All India Institute of Medical Sciences (AIIMS), New Delhi, India

## Introduction

Creatinine is a nonprotein nitrogenous compound found in the blood and excreted by glomerular filtration at a constant rate (Feher 2012).

## Source

Creatinine is derived from nonenzymatic degradation of creatine phosphate which is a phosphagen for vertebrate animals. Phosphagens are high-energy phosphate compounds which supply immediate but limited energy during sudden demand for skeletal muscle and brain. Creatine phosphate is a phosphagen for vertebrate animals, whereas arginine phosphate is the phosphagen for invertebrate animals.

Adenosine triphosphate (ATP) is the energy currency of the cell required for many biochemical reactions. During the sudden demand for ATP, creatine phosphokinase enzyme catalyzes the transfer of phosphoryl group from creatine phosphate to adenosine diphosphate (ADP) to produce adenosine triphosphate (ATP). This reaction is known as Lohman's reaction.

A fraction (around 1–2%) of creatine and creatine phosphate are spontaneously

(nonenzymatically) and irreversibly converted into creatinine in skeletal muscle. Conversion of creatine to creatinine involves dehydration (removal of water). Amount of creatinine produced in an animal is constant and related to the muscle mass. A 70-kg adult male produces about 2 g of creatinine per day.

## Creatinine Clearance

Creatinine clearance is the volume of blood that is cleared of creatinine in 1 min. Creatinine is a small molecule with the relative molecular weight of 113 Da (Stevens et al. 2010). It is present in most of the body fluids and secretions. In the renal glomeruli, creatinine is freely filtered by the glomerulus because of the low molecular weight. Then, it is not reabsorbed and excreted without any alteration with the minimal secretion of creatinine by the renal tubules. Because of this property, creatinine is used as a marker of glomerular filtration rate (GFR) (Huidobro et al. 2018). Thus, creatinine clearance slightly overestimates the GFR.

Urea is another nonprotein nitrogenous compound excreted by the kidney. Urea clearance can also be used for GFR estimation. The advantage of creatinine clearance over urea clearance is given in the table.

| Urea clearance                      | Creatinine clearance             |
|-------------------------------------|----------------------------------|
| Underestimates GFR                  | Overestimates GFR                |
| Inferior to creatinine clearance    | Better than creatinine clearance |
| Depends upon flow rate              | Independent of flow rate         |
| Depends upon dietary protein intake | Independent of dietary proteins  |

The mathematical formula to calculate creatinine clearance is:

$$\text{Creatinine clearance} = \frac{\text{Urinary creatinine (mg/dl)} \times \text{Urine flow rate (ml/minute)}}{\text{Serum Creatinine (mg/ml)}}$$

The unit of creatinine clearance is ml/minute. Urinary creatinine is calculated using a urine sample collected over 24 h. As the 24-h collection of urinary samples is difficult, Cockcroft-Gault formula is widely used to find out estimated GFR (eGFR) from serum creatinine values in humans (Shoker et al. 2006).

$$\text{eGFR} = \frac{(140 - \text{age in years}) \times \text{Weight(Kg)} \times K}{72 \times \text{serum creatinine (mg/dL)}}$$

$K = 0.85$  for women and 1 for men

## Clinical Significance

In combination with serum urea level, creatinine clearance provides an important clue to the diagnosis of renal diseases especially renal failures. Different composite and surrogate markers of renal function utilize creatinine concentration, e.g., blood urea nitrogen (BUN)/creatinine ratio.

## Methods of Creatinine Estimation

Creatinine is estimated commonly by a chemical method using its reaction with picric acid (Jaffe's method). Protein, ketones, bilirubin etc. are known interfering substances in this method. In dry chemistry analyzers, enzyme (creatininase, creatinine deaminase)-based methods are used.

## Crepuscular

Nora V Carlson  
University of St Andrews, Fife, UK

## Synonyms

[Bimodal activity pattern](#); [Matutinal \(active at dawn\)](#); [Twilight](#); [Vespertine \(active at dusk\)](#)

## Definition

Crepuscular refers to twilight, the time shortly before sunrise and after sunset. In the context of animal ecology, it refers to those species active during these times of day. In other words, a crepuscular animal is one whose diel (24 h) activity pattern has peaks during the twilight hours (e.g., African wild dogs). Crepuscular can also be used to refer to specific behaviors of non-crepuscular species that usually occur during twilight (e.g., nocturnal smooth-tailed newts are crepuscular breeders).

## Crepuscular Behavior Patterns

Crepuscular organisms are those that are primarily active during the twilight hours: the periods just around dawn and dusk. Astronomical twilight occurs when the sun is between 0° (sunrise/sunset) and 18° below the horizon (Potts 1990). Twilight near the equator lasts approximately 70 to 85 min, though it can be much longer at higher latitudes. The light levels change dramatically during this time; within 30 min light levels can change from 100 to 0.01 lux (or vice versa; Potts 1990).

The activity patterns of crepuscular species are often referred to as being bimodal unless they are either matutinal, active only at dawn, or vespertine, active only at dusk. While species that are classified as being crepuscular exhibit their peak activity during these hours, some crepuscular species will also be active at specific times of day or night. This is because the quantity and quality of light is the ecologically relevant determining factor of crepuscular activity, not the time of day. In fact, many crepuscular species will be active in light conditions similar to twilight that occur at other times of the day as well (i.e., full moon nights, or heavily overcast days).

Species displaying crepuscular activity patterns are not the only ones who are active during these twilight periods. Many diurnal (species active during the day) and nocturnal (species active during the night) animals are also active during this time. This twilight period acts as a transition period with diurnal and nocturnal species tapering off their level of activity in preparation for a period of inactivity or ramping up in preparation for their active period. Cathemeral/metaturnal (active at regular intervals irrespective of time of day) species also frequently overlap their activity patterns with crepuscular species depending on their diet or local predation pressures.

While species whose main peak of activity occurs during twilight are considered truly crepuscular, many other diurnal or nocturnal species have crepuscular behavior patterns, i.e., behaviors they exhibit only during the dawn and/or

dusk. Smooth newts, *Triturus vulgaris*, for example, are primarily nocturnal species yet breed only during dusk (Griffiths 1985). Diurnal passerines are well known for their dawn and dusk choruses, exhibiting a peak in singing behavior most commonly at dawn, but for some species during dusk as well (Kroodsmas and Miller 1996). Many species of diurnal and nocturnal marine fish show crepuscular traveling behavior as they travel between foraging areas and the safety of burrows where they remain protected during their inactive periods (Potts 1990). Other species, such as Carangidae and Elopidae species, show crepuscular peaks in foraging activity as they take advantage of the diurnal and nocturnal species that have begun their transition too late or too early. In fact, it can often be difficult to classify a species' activity patterns as crepuscular as there can be so much overlap in the patterns of diurnal and nocturnal species making the boundary between crepuscular and nocturnal or diurnal less clear. This delineation is especially difficult when species are reacting to local conditions (such as moonlight levels or local heterospecific competitors or predators) causing shifts in their normal activity patterns making them appear more or less crepuscular than other populations.

## Prevalence of Crepuscular Activity Patterns in the Animal Kingdom

Crepuscular activity patterns are widely prevalent, with most taxa having at least a few species that exhibit this diel pattern. While crepuscular activity patterns are relatively rare in birds, reptiles, and amphibians, crepuscularity is more common in fish such as carangids, lutjanids, serranids and in some gadoids, as well as in many species of insects (Griffiths 1985; Hall and Ross 2006; Kelber et al. 2006; Potts 1990; Shine 1979). Crepuscular patterns appear more common in mammals as, while visible or somewhat active during either the day or night, mammals likely had a nocturnal ancestor, and many mammals are actually crepuscular, ramping up their activity at dawn and dusk (Halle 2006).

## Driving Forces Behind Crepuscular Diel Patterns

There are a number of theories as to why crepuscular activity patterns have evolved in such a wide range of species, but the two most common are related to either predation or competition. During twilight, as the sun sets or rises, the light changes very quickly. This rapid shift in light intensity causes many species to have trouble seeing (Caro 2005; Hayward and Slotow 2009; Potts 1990). This allows predators, even diurnal or nocturnal ones, to take advantage of the unique light conditions to catch prey that cannot detect them as easily (Hayward and Slotow 2009; Potts 1990). Although these easily caught prey should avoid this time of day, often being active during twilight is unavoidable as they are either preparing for or recovering from long periods of inactivity and can be a profitable food source for crepuscular predators (Halle 2006). Some crepuscular predators are driven more by the behavior of their prey, as opposed to the quality of light. For example, many species of marine fish follow plankton as it rises during dusk engaging in vertical migrations, while common murre, *Uria aalge*, that prey on these fish, such as capelin, *Mallotus villosus*, will peak in foraging activity as the fish migrate close to the surface (Potts 1990; Regular, Davoren, Hedd, and Montevecchi 2010). Similarly, many snake species, such as Australian elapids, will take advantage of mammals that leave their burrows at dusk (Shine 1979). For the predators that rely on these food sources, their peaks in activity tend to be related to searching for and catching these prey, thereby shaping these predators' activity patterns to follow a crepuscular or, in these cases vespertine, pattern.

Some frequently depredated species, similar to many predators, take advantage of these twilight light conditions that limit a predator's ability to visually detect them, thus lowering their chances of being depredated (Caro 2005). However, simply avoiding predators may be an even stronger drive. It is thought that the dawn, and or dusk, chorus in passerine birds occurs at twilight due to fewer predators actively hunting then, allowing these vulnerable species to sing from exposed

perches, a highly dangerous behavior (Kroodsma and Miller 1996).

While predation is a strong driving force that shapes the natural history of many species, competition, especially over food, is similarly important. Some bee species in the Andrenidae and Halictidae families, for example, take advantage of nocturnal flowers that open at dusk thereby maximizing the pollen load they can collect. By being active before the nocturnal species that visit those flowers are, these crepuscular bees gain a competitive advantage (Kelber et al. 2006). Crepuscular foraging may also help in cases where competitors also pose a risk. In the African savanna, the less dominant large carnivores, cheetah and wild dogs, are most active in a diurnal/crepuscular, or strictly crepuscular patterns, respectively (Hayward and Slotow 2009). This crepuscular activity is likely due to avoidance of competition, and possible dangerous interactions, with more dominant nocturnal carnivores, lions, leopards, and hyenas, as these activity patterns do not overlap with those of cheetah or wild dog preferred prey (Hayward and Slotow 2009).

## Adaptations for Crepuscular Behavior

As previously mentioned, twilight light quality is such that the combination of the quick change and quality of light makes it difficult for the rods and cones found in vertebrate species to operate well, resulting in decreased visual acuity and sensitivity in these light conditions (Caro 2005). Many species that follow crepuscular activity patterns have evolved features that help them adjust to these specific visual conditions. Crepuscular birds, for example, have an intermediate relationship between their visual acuity (telling objects apart) and their visual sensitivity (the ability for the eye to gather light) as opposed to diurnal birds with high visual acuity compared to sensitivity and nocturnal birds with high visual sensitivity compared to acuity (Hall and Ross 2006). This intermediate level of acuity and sensitivity allows them to cope with the specific light conditions during twilight hours (Hall and Ross 2006). Additionally, coloration or markings around the eye may also help species adjust to

these difficult light conditions. Dark eye patches are found more frequently on crepuscular species and are thought to serve an anti-glare function. This would allow crepuscular animals with eyes more well adapted to lower light conditions deal with higher intensity light, thereby allowing these species to see well across a wide range of light conditions (Caro 2005).

## General Conclusion

While truly crepuscular species are rarely described, the difficulty in determining the exact boundary between crepuscular and diurnal or nocturnal activity patterns combined with a bias toward diurnal and nocturnal activity pattern categorization suggests that more species than often reported may, in fact, be crepuscular. Additionally, while crepuscular as a descriptor is most often used for a species' peak activity patterns, many species have specific crepuscular behaviors, or simply continue past their normal active times into the twilight.

## Critical Period for Song Learning

Ednei Barros dos Santos  
University of Lethbridge, Lethbridge, AB,  
Canada

### Synonyms

Sensitive period for song learning; Sensory acquisition phase

### Definition

A species-specific developmental time window in which juvenile songbirds are especially sensitive to auditory input and are able to readily memorize the song patterns of conspecific adults.

### Introduction

Songs are an essential trait of songbirds and serve multiple communicative functions. They are used, more commonly, by males to attract and stimulate the reproductive behavior of females, to advertise territory ownership, and to mediate competition between rival males (Collins 2004). Although the process of song learning in songbirds has attracted attention and received contributions from several fields, including ethology, behavioral ecology, genetics, and neurobiology, it still stands as a major evolutionary puzzle. Song learning has drawn so much scientific interest, in part, due to its similarity to the process of language acquisition. Songbirds share with humans the very distinctive ability of vocal learning. This ability evolved in only three groups of birds (songbirds, hummingbirds, and parrots) and in few mammals (Jarvis 2004). Song learning in songbirds in many ways resembles the steps a human infant follows during the acquisition of a native language (Doupe and Kuhl 1999). As in humans, vocal learning in songbirds initiates early in life. In most species, a critical period for song learning

starts just after young birds leave their nests. However, the time span in which the learning process takes place and the detailed ways in which song patterns are learned vary widely across songbird species.

### The Study of Bird Song Learning

The scientific study of bird song learning initiated with the seminal studies of the British ethologist W. H. Thorpe. He was responsible for introducing the use of sound spectrograms to conduct research in bird song. This technique consists of the production of visual representations of sounds as plots of frequency against time, allowing the inspection and analysis of the structure of songs in fine-grain details (Thorpe 1954). For the first time, it was possible to visualize the basic components of songs. “Notes” were identified as continuous traces in sound spectrograms. “Syllables” were defined as regular groupings of notes forming units. Sequences of syllables form “phrases” and different combinations of phrases form different “song types.”

Thorpe initiated a series of studies on song learning during the 1950s using chaffinches, *Fringilla coelebs*, as his species model. His approach to the study of song learning consisted of taking wild birds from their nests at a few days of age and subsequently rearing them by hand in sound-proof rooms. He would then perform different kinds of experiments by keeping juvenile birds acoustically isolated and by carefully exposing them to tape-recorded adult songs. For example, Thorpe (1958) demonstrated that juvenile chaffinches reared in acoustic isolation (unable to listen to adult songs) develop abnormal songs. These songs had the species-specific frequency spectrum and duration but lacked many details in the structuring of notes and syllables found in normal chaffinch songs. On the contrary, hand-reared birds exposed to tape-recorded adult songs within a specific time window early in life would develop normal songs similar to those produced by wild chaffinches. These first set of experiments revealed that songbirds learn their songs early in life. In addition, they need to be exposed to adult

songs within a critical or sensitive period, a time window in which juvenile songbirds need to be exposed to adult songs in order to successfully develop normal species-specific songs.

## The Phases of Song Learning

Another important contribution made by Thorpe (1959) was the suggestion that juvenile songbirds show a bias for learning their own species-specific songs over songs from other species. This prompted him to propose the idea that songbirds are born with an endogenous “blueprint,” an innate mechanism that guides juvenile birds throughout song ontogeny by allowing them to select and focus their attention on conspecific songs; thus, filtering out songs from heterospecific males available in their environment.

### The Auditory Template Theory

Thorpe’s seminal studies provided the framework for the later theoretical development of the auditory template theory (Konishi 1964; Marler 1976), the leading and most influential model on the process of bird song learning. This model proposes that song learning goes through a two-stage sensorimotor development process. First, a sensory acquisition phase takes place. This is a period of sensitivity to auditory input in which song patterns of adult conspecifics are readily memorized. This stage is then followed by the sensorimotor phase, during which the motor development of vocal production occurs, guided by the memory of adult songs stored in the sensory acquisition phase. Although initially based on studies conducted on chaffinches and white-crowned sparrows (*Zonotrichia leucophrys*), subsequent studies have shown that the general patterns of these phases are widely shared among songbirds.

### Sensory Acquisition Phase (or Critical Period of Song Learning)

In songbirds, song learning initiates with a sensory acquisition phase. This phase is often defined

as the critical or sensitive period for song learning. During the sensory acquisition phase, juvenile songbirds are able to readily memorize the song patterns of adult conspecifics. Later on, they use the stored memory of adult songs as a model that guides the vocal motor phases of song development. The detailed aspects of the critical period show great variation across species. Songbird species can differ in factors such as the timing and length of the critical period, the level of selectivity of auditory input and the relevance of social interaction. These factors will be detailed below.

### Sensorimotor Phase

After memorizing the song patterns of adult conspecifics, juvenile songbirds go through a process of vocal motor development, called sensorimotor phase. This phase consists in the progressive development of a vocal motor program (Marler 1991) in which the singing output is guided by the stored memory of adult songs heard during the sensory acquisition phase.

### Subsongs

Songbirds produce *subsongs* at the earliest stage of vocal motor development. Subsongs have been compared to human baby babbling, because they hardly resemble fully-developed adult songs. They are quiet and show high variability of notes and syllables. It is hypothesized that singing at this stage functions as a way to develop fine sensorimotor control and to train the vocal apparatus (Hultsch and Todt 2004).

### Plastic Songs

Following the production of subsongs, juvenile songbirds go through a stage in which they start to produce louder songs that are structurally closer to those of adult males, these are called *plastic songs*. The songs produced during this stage already contain many elements found in adult songs, but these are still not stable stereotyped songs. In fact, plastic songs in some species are characterized by an overproduction of song elements, resulting from improvisation and/or error in the imitation of the adult songs memorized at

the sensory acquisition phase. However, not all of these novel elements are preserved in the fully developed adult songs.

### Crystallized Songs

The last stage of vocal sensorimotor development occurs when individuals are approaching sexual maturity. At this stage, songbirds start to produce *crystallized songs* and the structure of songs is already stable and acquires stereotyped characteristics similar to those of the adult songs memorized during the sensory acquisition phase. In some species, there is also a selection of which elements will be incorporated into the songs used later in adulthood.

### The Role of Auditory Feedback

The absence of auditory feedback during the sensorimotor phase of song learning can drastically constrain the development of normal songs. Juvenile songbirds that are unable to listen to their own singing develop songs lacking the structure of their normal species-typical songs. These abnormal songs show severe distortion in its basic component elements. Individuals deafened at earlier during the sensorimotor phase produce abnormal songs with higher levels of distortion in the structure of notes and syllables (Konishi and Nottebohm 1969). The crucial relevance of auditory feedback for the development of normal song has been supported by a set of studies conducted on experimentally deafened songbirds. For example, juvenile white-crowned sparrows deafened before the sensorimotor phase develop abnormal songs (Konishi 1965). Similar results have been reported for swamp sparrows, *Melospiza georgiana*, and song sparrows. Individuals of both species deafened between 17 and 23 days of age (prior to the onset of the sensorimotor phase) develop abnormal songs. However, some species-typical characteristics are still noticeable in these abnormal songs. For example, the high degree of element segmentation, present in the structure of normal song sparrows' songs, is still preserved in abnormal songs (Marler and Sherman 1983).

### The Timing and Length of the Critical Period

In most species, the sensory acquisition phase or critical period for song learning starts just after young birds fledge (Catchpole and Slater 2008). However, the timing and length in which this phase takes place vary dramatically between different species. For example, in white-crowned sparrows, the length of the critical period for song learning is restricted to the first months of life. Marler (1970) performing a, now classic, acoustic isolation experiment found that hand-reared juveniles develop normal songs if they are exposed to tape-recorded adult songs between 10 and 50 days of age whereas juveniles exposed to adult songs outside this 40-day period developed abnormal songs (Marler 1970). In other species, however, the critical period can last for the entire first year of life, as in chaffinches (Lachlan and Slater 2003) or it can even last for the entire lifetime in species that never cease to incorporate new elements to their songs, such as canaries, *Serinus canarius* (Nottebohm et al. 1986).

### Close-Ended and Open-Ended Learners

Traditionally, songbirds have been classified as *close-ended learners* (or age-limited) and *open-ended learners*. Close-ended learners include species in which individuals learn songs only up to a certain age, usually within the first year of life. Within this limited period, juveniles learn all song types that they will then sing for the rest of their life. The groups of open-ended learners comprise species in which individuals also start the song acquisition process early in life, but keep adding new song elements to their repertoires throughout life. The accumulated evidence about the detailed mechanism of song learning in different species has challenged this traditional classification. A large number of factors, including the level of selectivity of auditory input and the relevance of social interaction are now known to affect the timing and length of the critical period for song learning. Additionally, studies on song learning are rarely conducted beyond the first year of songbirds' lives. So, long-term research encompassing

multiple years might reveal that some species that we now think are close-ended learners are in fact open-ended learners, i.e., they continue to add new elements to songs in adulthood (Beecher and Brenowitz 2005).

### What Is Learned During the Critical Period?

The auditory template theory proposes that the brains of juvenile songbirds are not *blank slates*. According to this model, songbirds are born with a rudimentary representation of their species-typical songs, an auditory template. This template plays a fundamental role throughout the process of song acquisition. It is supposed to allow juvenile songbirds to recognize and learn songs, preferentially, from males of their own species during the sensory acquisition phase (Marler 1970; Thorpe 1958). Some studies conducted during the sensory acquisition phase, before juveniles are able to produce songs, have supported the idea that songbirds have an innate ability to discriminate their species-specific songs. For example, hand-reared swamp sparrows around 20 days of age have lower heart rates when exposed to conspecific songs than when they listen to songs of song sparrows, a closely related species (Dooling and Searcy 1980). Also, juvenile white-crowned sparrows, between 12 and 23 days of age, produce a higher number of begging calls when exposed to songs of conspecific males than when exposed to songs of heterospecific males (Nelson and Marler 1993). In addition, in many species, if juveniles are simultaneously exposed to conspecific and heterospecific songs, they will preferentially learn conspecific songs (Marler 1970).

The auditory template seems to create a preferential bias for input from conspecific songs. However, the detailed way in which song patterns are learned, might work differently even in closely related species. Some species have a rigid template and learn only song elements that closely fit to their template, whereas other species are much more flexible and can incorporate even song elements of other species. For example, juvenile

song sparrows, tape-tutored with both conspecific songs and song sparrow songs, are able to learn their own species songs and also swamp sparrow songs, whereas swamp sparrows exposed to the same song stimuli can learn only conspecific songs (Marler and Peters 1989). Cross-fostering studies offer another way to analyze the selectivity of auditory input and preferential bias. In this research approach, young songbirds are raised by adults of another species as a way to examine the degree in which different auditory input might influence song preference and development. Young zebra finches, *Taeniopygia guttata*, fostered by Bengalese finches, *Lonchura striata domestica*, later when adults, exhibit reduced discrimination of conspecific songs. They also demonstrate preference for Bengalese finch songs over conspecific songs (Campbell and Hauber 2009).

### Memory-Based Learning

Acoustic isolation experiments have shown in some species that exposition to adult songs exclusively during the sensory acquisition phase is sufficient to generate memories that will then guide the remaining process of vocal development. Juveniles from some species are able to memorize adult songs very accurately even when they have been exposed to it few times. Song sparrows, *Melospiza melodia*, for example, are able to memorize songs heard only 30 times during the sensory acquisition phase (Peters et al. 1992). In the majority of songbird species studied so far, there is a time gap between the end of the sensory acquisition phase and the onset of the sensorimotor phase. Hence, at the start of vocal motor development, juvenile songbirds need to access the stored memory of songs heard several weeks or even months before (Marler 1991). Zebra finches, though, are a noticeable exception. In this species, there is a time overlap between the sensory phase and the sensorimotor phase. Juvenile zebra finches start producing subsongs while still memorizing adult songs. Their critical period for song learning ranges from 25 to 65 days of age. However, after reaching 35 days of age, juveniles already start to vocalize subsongs (Zann 1997).

## Social Influences on Song Acquisition

### Tape Tutoring Versus Live Tutoring

Social interaction with conspecifics has been identified as a factor that can greatly influence the process of song learning. Some experiments using live tutors, instead of tape-recorded songs, have shown that social factors have a major relevancy on the process of song acquisition and can affect even the time span of the sensory phase of song learning. For example, juvenile white-crowned sparrows exposed to songs of live conspecific tutors can have their sensory phase extended beyond the typical 10–50 days found with tape-recorded song tutoring. Social interaction with live tutors can extend the sensory phase up to 200 days of age (Baptista and Petrinovich 1986). Two studies investigating song learning in song-sparrows show contradictory results from tape tutoring versus live tutoring. Tape-tutored song-sparrows learn most of their songs before 90 days of age (Marler and Peters 1989). On the other hand, song sparrows exposed at different ages (between 30 and 90 days and between 140 and 330 days) to the songs of two groups of live tutors learn most of their songs from late tutors than from early tutors (Nordby et al. 2001). In other species, tape-tutoring can be completely ineffective. In tree creeper species, *Certhia* spp., for example, social interaction is so relevant for song acquisition that juveniles are able to learn songs only from live tutors (Thielcke 1984).

### Selective Learning

Songbirds are exposed to and learn more song elements than they eventually use during adulthood. The detailed mechanism by which juveniles select their song repertoire is still unknown. Nonetheless, some studies indicate that social interactions can determine which song elements learned at the sensory acquisition phase are retained at song crystallization to be later used in adulthood. For example, in brown-headed cowbirds, *Molothrus ater*, the song acquisition process is also influenced by the social interaction with conspecific females. Juvenile birds in this species favor the crystallization of songs that better elicit mating responses, wing strokes, in

females (West and King 1988). The importance of social interaction as a determinant of song learning has pushed Nelson and Marler (1994) to propose a mechanism named “selective attrition” (or action-based learning) as an addendum to the auditory template theory. Contrary to the auditory template theory, this mechanism is not based on instruction and passive exposition to auditory content. In fact, it suggests that the selection of song elements during the song crystallization phase is an active process in which songbirds are able to retain song patterns that are better suited to their social environment. For example, Nelson and Marler (1994) showed that juvenile white-crowned sparrows, during the song crystallization phase, retain song-types that better match the regional variations on song-types (song dialects) sung by neighboring males.

## Conclusion

Around 60 years ago, researchers began to develop a scientific understanding of the developmental process through which juvenile songbirds learn their species-typical songs. Early studies indicated the existence of a critical period for song learning. Juvenile songbirds need to be exposed to conspecific adult songs within a species-specific time window in order to develop normal species-typical songs. Within this critical period, the memorization of song input is facilitated and the stored memories of adult song patterns guide the remaining stages in the process of song acquisition. Subsequent research has provided general support for the majority of these pioneering ideas and largely expanded the number of studied species. At the same time, new studies have shown that many species do not have a well-defined critical period for song learning. Additionally, the timing and length of the critical period are now known to be dramatically affected by social factors.

## Definition

The term critical period can be defined as a temporal window in an organism's life when an experience or an external stimuli has a heightened, irreversible impact on the development of its physiology, morphology, cognition, and behavior.

## Introduction

An organism's ability to interact and adapt to its changing environment is one of the decisive features for its survival. Such feat could only be accounted for a system which is not only able to efficiently process information tailored to its surroundings but would also be able to evolve over its lifespan. Thus, it is the emergence of this system in the early developmental phase of life which allows the organism to exist and even thrive in unfamiliar environments. Indeed, a particular arrangement of brain circuitry is the physical manifestation of such a system which generates an adaptive behavior. In that context, it is important to discuss "sensitive period," a brief window of time when the influence of an external stimuli on

this circuitry is strong enough to significantly modify its organization. Often, these alterations persist; however, they are prone to further changes throughout the organism's lifetime. This is known as "brain plasticity" and allows the possibility of lifelong learning. While the exact role of sensitive period is still unclear, it might play a foundational role in laying the core circuitry when the animal is in its developmental stage and any changes of learning which occurs afterwards happen within its structural constraint (Knudsen 2004). Seemingly, these modifications lead to an arrangement which is tailored to that specific environment and consequentially confers an adaptive advantage. Hence, a period of enhanced learning plays a pivotal role in guiding the organism through a new environment while it's still young and vulnerable, such as in the case of filial imprinting in ducklings (discussed further in section "[Behavioral Imprinting](#)") (Bolhuis and Honey 1998).

"Critical period" can be defined as an extreme form of sensitive period where the impact of the environment on the brain circuitry is permanent and irreversible. What's more, a lack of proper input during this window often leads to loss of function (Knudsen 2004). For example, when cats were exposed to visual input with their one eye shut during the critical period, they developed a condition known as amblyopia in which there was a loss of visual acuity in the closed eye (discussed in section "[Biological Mechanism of Critical Period: Plasticity in Visual Development](#)"). It was also noticed that depriving the input before or after the critical period did not affect normal vision development (Hubel and Wiesel 1962). Hence, critical period can be characterized by a specific opening and closing period along with a unique input signal. It is worth noting however that the input signal itself drives the onset and closure of this window rather than a timed maturational event. Hence, critical period can be delayed if there is a lack of proper input, or may not even begin in the first place (Knudsen 2004).

A time-restricted window of development acts as a double-edged sword. There is always a possibility that anomalous experiences during this phase can permanently leave its impression on the brain circuitry. Critical period, however, ensures that the acquired experience which is

imprinted on the brain is protected from being overwritten with new information. Thus, there is a trade-off between adaptability during this period and stability later on (Knudsen 2004).

## Behavioral Imprinting

Imprinting can be described as a learning process that is rapid and occurs within a particular time range, usually resulting in the formation of behavioral association to a certain stimuli. This term was first elaborated by a well-known zoologist and the father of modern ethology Konrad Lorenz based on his study on goose and duck younglings. Lorenz observed that these juveniles have a tendency to follow their mothers soon after hatching and this learning process only happens during a fixed window of time, which he termed as *critical period*. This phenomenon was consequentially known as *filial imprinting* (Bolhuis and Honey 1998).

In a series of experiments performed by Lorenz, he found that he could imprint this behavior to a substituted object if presented during the critical period. By exposing himself to newly hatched ducklings (visual stimuli) and mimicking the quacking sound of mother duck (auditory stimuli), he was able establish bonding which resulted in a similar behavior. The ducklings would even react to inanimate objects such as a red ball and begin to follow it. Filial imprinting is displayed mostly in species whose progeny are born in a relatively developed stage, so much so that they could easily wander away from their parents. This learning process ensures that the newly born stick close to their mothers as they are still dependent on them for food and shelter till the time they mature. Such species are called precocial species. This is in contrast to altricial species whose young ones are not so developed and consequentially no filial imprinting is observed as such (Mackintosh 1974).

Imprinting has been investigated in other areas as well, such as the preference for sexual partner (sexual imprinting) and the formation of social bonds (social imprinting). Sexual imprinting occurs when a species' preferred mate choice is guided by its early exposure to the characteristics

of its parents. This phenomenon has been well documented in studies concerning zebra finches, where, the young male, if reared under the female Bengalese finches (these finches have a tendency to easily accommodate members of other species), become inclined to mate as they mature with the members of the foster specie over their conspecific counterparts. This learning process seems to have a critical period and is irreversible. Sexual imprinting in birds is observed in almost half of the taxonomic order and implies a strong role in the unfolding of the evolutionary dynamics involved in maintenance of the speciation process. Speciation occurs when a population isolates and evolves to become a different species; thus, sexual selection and species recognition ensure low chance of interbreeding if the isolated populations ever comes back in contact (Immelmann 1972).

The formation of social bond within a time-sensitive period is phenomenon that is well accepted as seen by multiple incidences in nature. A classic example would be of slave-maker ants which display brood parasitism – reliance on other specie for the rearing of its younglings. These ants are known to steal the eggs and larvae during raids on ant colonies of different species. When the eggs hatch, these ants get socially imprinted and integrate in the new colony and help raise the larvae of its captors (Blatrix and Sermage 2005).

## Critical Period in Vocalization

### Songbird Learning

Songbirds belong to the suborder of *Passeri*. These perching birds have evolved an elaborate system to produce complex patterns of sounds (referred to as “song”) which could be distinguished from simple calls such as that of a pigeon. Indeed, this complexity is necessary for executing high-order behaviors which has been observed in mate call and territoriality. The mechanism underlying the development of communication in songbirds shows a strong overlap with humans and, hence, has been extensively studied by the researchers. The entire process could be distinguished into three phase, viz., sensory learning, sensorimotor integration, and song crystallization.

During the sensory phase, the hatchling is tutored by an adult male which exposes them to its species-specific song. This learning has a critical period (15–60 days in zebra finches) in which the song pattern is encoded in the brain. The sensorimotor phase is also characterized by a critical period which usually overlaps with sensory phase (30–90 days in zebra finches). The tutored youngling produces a series of vocal elements using the memorized template till it is able to match the adult song. Eventually, a surge in the testosterone levels leads to a song being permanently crystallized. It is important to note that songbirds such as canary and greenfinches could also display a seasonal cycle of learning, repeating the processes annually. However, in many species such as the zebra finches, chaffinch, and white-crowned sparrow, song learning happens only once in a lifetime (Merrill et al. 2017).

The existence of the different phases in song learning gives interesting insights in the organization of multiple critical periods. Hatchlings which were reared in solitary environment or were tutored beyond critical period did not make any stereotypical bird song. Rather, a distorted version of the song was produced, though still retaining some vocal qualities specific to the specie. Delay in early song exposure could even lead to an extension in the critical period for sensory learning, sometimes even stretching into adulthood. Moreover, the hatchling only respond to songs of their own species and even display a preference. This shows that genetic specification plays an important role in biasing the neuronal circuits towards a certain stimulus (Merrill et al. 2017).

### **Biological Mechanism of Critical Period: Plasticity in Visual Development**

A time-dependent behavioral outcome is one of the distinguishing features of the critical period. These changes often reflect a shift in the brain plasticity, usually at the level of synapses. Such chain of events unfolds to morph a system which is highly receptive towards a particular stimulus till the desired connectivity of neurons is established. Fundamentally, this signifies that the circuitry in the

brain “competes” for the desired input, and synapses which respond actively to the signal are selected and enhanced while the rest are pruned out. This process is known as activity dependent competition (Hensch 2004). Thus, critical period must have a transient “opening” and a “closing” window followed by the consolidation of such circuitry. As mentioned previously, such a mechanism would not only aid multiple systems to evolve independently but will also prove crucial when a matured circuit is needed to serve as a scaffold for the emergence of other systems (Schaefer et al. 2017).

To understand the physical basis of such event, one can look into the development of vision in animals: arguably one of the most explored sensory systems yet. The famous monocular deprivation experiment by Hubel and Wiesel in the early 1970s has described the effect of activity dependent competition during critical period. The visual cortex in adults contain a layered arrangement called ocular dominance columns which are biased towards input from one eye over the other. Indeed, an interrupted visual input from the eye during the early developmental phase of the animal is crucial for its formation. Animals who were reared with one eye shut responded only to visual input from the uncovered eye. Additionally, not only the ocular dominance region for the covered eye was absent but were taken over by the regions which responded to the uncovered eye (Schaefer et al. 2017).

Interestingly, the experience itself regulates the “opening window” of the critical period. Hence, a delay in the initial input can extend the duration of this window, though it varies from one system to another. In visual development, the maturation of GABAergic circuits, which are the principle inhibitory neuronal networks in the brain, dictates the opening and closure of the critical period. The exact mechanism is yet to be discovered; however, it is believed that this inhibition helps in the consolidation of the circuit via pruning of the nonessential synapses. Additionally, the heightened plasticity during initiation is believed to be a result of induced long-term depression (LTD) by the aforementioned inhibitory circuit. Another key component for the closure of critical period is the involvement of perineuronal net (PNN).

These extracellular structures stabilize the inhibitory synapses by enwrapping the parvalbumin-expressing GABAergic interneurons (PV cells). An inhibition of the visual input can interfere with maturation of PV cells, thereby hindering its interaction with PNN leading to a delayed closure of CP (Schaefer et al. 2017).

## Discussion

What makes critical period unique is also what makes it immensely difficult to characterize. A transient period of heightened plasticity does not always indicate that experiences cannot have a lasting effect later in life. After all, lifelong learning is what enables an organism to alter its behavior in response to a changing environment. Critical period, however, could be described as an extreme form of sensitivity where environmental input instructs the very organization of brain circuitry, and this initial foundation is what opens new avenues for future learning. This raises a possibility that even arbitrary disturbances, no matter how minuscule or sparse can steer the direction of cortical development and affect resulting behavior (Nelson and Gabard-Durnam 2020). It is difficult to establish a causal relationship between critical period and many developmental ailments given our limited understanding of it. However, compelling evidences keeps piling up, for instance, researchers are now considering that disorders such as Autism might actually be due to altered plasticity during maturation (LeBlanc and Fagiolini 2011). Additionally, few researchers have even managed to perform interventions in animals by artificially reopening the critical period via pharmacological manipulation of the inhibitory circuits. Thus, reimagining these anomalies as critical period disorders may lead to novel therapeutic strategies reorienting the altered trajectory of development (Hensch and Bilimoria 2012).

## Introduction

Crocodilians (crocodiles, caimans, alligators, gavials, and their kin) superficially resemble large lizards, but they are in fact more closely related to birds, with which they share many behavioral, and presumably cognitive, characteristics. Both belong to the Archosaur clade, which included dinosaurs and pterosaurs, as well as the ancestors of the present day crocodilians. The pterosaurs and most of the dinosaurs succumbed to a catastrophe, usually attributed to a meteorite impact at the Permian-Triassic boundary. However, one group of dinosaurs, the birds, survived and still dominates the landscape in most parts of the world. The ancestors

of the crocodilians were diverse, often terrestrial predators, but all present-day members of this lineage are semiaquatic predators living at the interface between land and water.

The legacy of their terrestrial ancestors is revealed when crocodilians walk with their bodies held high off the ground with the legs propped almost vertically in contrast to the splayed-legged gait of lizards. Some crocodilians will even gallop if they need to return quickly to water, but the legs are generally used only to steer the body in shallow water. Most of a crocodilian's propulsive power comes from sweeps of its powerful tail through the water, and this restricts its foraging strategies and the vulnerability of different types of prey.

## Food and Feeding Habits

The metabolism of crocodilians is very slow, which has the advantage that they use energy very efficiently and do not have to feed frequently (Coulson and Hernandez 1983). Small- and medium-sized crocodilians can go for months without feeding, and the largest individuals can possibly survive fasts lasting several years. Many female crocodilians guard their nests during the two- to three-month incubation period, and if the nest is far from water she may not be able to feed. Female common caimans guarding nests far from water lose body condition during the incubation period in central Amazonia, but the time she can spend beside the nest may be more limited by water than energy.

The slow metabolism of crocodilians has allowed researchers to study digestive processes that would be impossible to study in typical laboratory animals, such as rats, so our knowledge of the basic physiology of digestion owes much to the study of crocodilians. The slow metabolism is not a primitive feature, and presumably the terrestrial ancestors of present-day crocodilians had much higher metabolic rates and more active life styles. Rather, it is an adaptation that allows crocodilians to obtain much higher densities and biomass per unit area than similar-sized mammals (Magnusson and Lima 1991).

Their low metabolic rates allow crocodilians to spend long periods under water, either to escape from predators or to remain concealed from their terrestrial prey. Crocodilians sometimes forage underwater, and some species are known to take terrestrial prey well away from water, but most of their prey, including aquatic organisms, such as fish, is taken in the shallows or close to the bank, so that the head is out of the water at the moment the jaws are swept toward the prey. The basic tactic for prey capture is therefore a forward lunge propelled by the tail combined with a sideways sweep of the long jaws. There are only minor variations on this theme, so most of the cognitive input in feeding relates to where and when an attack should take place for a given prey type.

Because crocodilian metabolism is tuned to low energy expenditure, they are not well adapted to prolonged activity. Strenuous exercise leads to a buildup of lactic acid in their tissues, to which they are more tolerant than most vertebrates, but they still have to rest to repay the oxygen debt. Prolonged struggling during capture can even lead to the death of large individuals, which have more difficulty flushing their muscles with oxygenated blood than do small animals.

People who are considered intelligent are often described as "quick," which implies that intelligence is associated with the ability to make quick decisions. However, a generally slow lifestyle and only small windows of time in which strenuous exercise is possible require complex planning and the ability to modify tactics during a feeding rally. Presumably, crocodilians need to keep complex maps in their heads in order to be in the right place at the right time to capture prey.

Some crocodilians, especially in the genus *Crocodylus*, undertake long annual migrations between feeding and breeding areas, some species make long marine voyages, and individuals have found their way back to their home ranges after being transported hundreds of kilometers along the coast to another river system. Young alligators have been shown to be able to use magnetic orientation to find their way home. Crocodilians therefore must have complex mental maps of the world, but it is unknown to what extent olfaction,

visual landscape features, magnetic compass orientation, and celestial navigation play in crocodilian movement planning.

Crocodilians are often described as having a generalist diet, which could give the wrong impression about how they feed. It is true that crocodilians are able to take advantage of most types of animal prey that are of the right size, so analysis of stomach contents of a large number of individuals will reveal a wide range of prey types. However, this does not mean that individuals wander around opportunistically taking any animals that come too close. At any one time, an individual is likely to be specializing on a particular type of prey and modifying its behavior to maximize the probability of contact with food that gives the highest return in terms of energy or nutrients.

Several species of crocodiles have been seen using their bodies and tails to corral fish in shallow water. The crocodile lies with its body parallel to the bank and uses its tail to block movement of fish along the bank or to sweep them toward the snout. When the fish tries to escape past the crocodile's head, it is grabbed by a sideways sweep of the jaws. The crocodile does not even need to see the fish, because it has pressure-sensitive pits along its jaws which are thought to be able to detect water movements caused by swimming prey.

Caimans have been observed waiting under frogs that call from trees, but lay eggs in the stream. Presumably, the caiman has learned that calling frogs eventually descend to the edge of the stream, often leading a female into the jaws of the caiman as well. During floods, the same caimans position themselves perpendicular to the water flow with the lower jaw just below water level and the upper jaw held just above it so that they can catch hapless animals being washed down. It is likely that both of these are learned behaviors.

One of the most spectacular sights on the East African savannas is the seasonal migration of wildebeest and other large ungulates. The herds cross the rivers at the same place each year and the crocodiles accumulate at these sites days or weeks before they arrive, indicating that crocodiles have very good long-term memories and can think ahead, as well as understanding spatial relationships.

Some caimans and crocodiles have been seen aggregated around canals where fish are funneled during migrations. Whether they find these aggregations alone, are only attracted by the concentration of other crocodilians, or are actively lead to feeding locations by other individuals is unknown. However, the latter is not unlikely. Caimans in the Brazilian Pantanal have been observed undertaking coordinated movements between pools in the dry season; one individual, usually the largest, leading the others, which follow in single file, sometimes for kilometers (Campos et al. 2003).

Because crocodilians often occur in large concentrations, social intelligence can be as important as hunting ability and not just because it is wise to follow the most experienced leader. Crocodilians have evolved into some of the most spectacular vertebrate killing machines that can bring down prey as large as themselves or, more importantly, kill another crocodilian with a single bite. Crocodilians do fight and kill each other, especially in territorial disputes. However, considering the high densities at which many species occur, fights are rare, and usually settled by one of the combatants showing submissive behavior, such as lifting its head vertically and revealing its throat.

Both crocodiles and caimans have been observed in narrow channels during fish migrations. Rather than attack haphazardly, the crocodilians form a line or a semicircle, all equally spaced, making a trap for the migrating fish. The predators do not break ranks even if the concentration of fish moves temporarily from one animal to another.

African crocodiles often have unexpected windfalls, such as a dead hippopotamus or elephant close to the water. Dozens or, in some cases, more than 100 crocodiles may gather at the carcass, but they can only feed from a small area of the soft underbelly, so the most efficient system is for them to take turns and that is exactly what they do, each individual waiting for their turn like gentlemen around a dinner table. Once an animal has pulled off a piece of meat, it moves out of the area to give the others access. There is obviously tension and all the crocodiles would probably like to be first to feed, but they apparently know their

position in a hierarchy of dozens or more individuals, even though they only encounter each other sporadically in the river.

Most aquatic habitats show strong seasonal changes in water depth, inundation of marginal vegetation, and the types of prey animal found on the banks. It is therefore likely that individuals of all species of crocodilians adjust their foraging behavior in relation to seasonal structural changes in the habitat and concentrations of different prey, and that they learn to adapt their behavior in expectation of changes before they occur, as has been shown for African crocodiles. However, because most crocodilians forage mainly at night and are secretive, especially if they have been hunted, there are no direct observations to back up these speculations.

All crocodilians must change their foraging tactics throughout their lifetime simply because their size, and hence the type of prey they take, changes drastically over time. Juveniles of all species are small, about as big as a medium-sized lizard, and they increase more than a thousand times in weight before becoming sexually mature; individuals of some species being among the largest terrestrial predators on the planet.

Crocodilians have conical teeth that vary in size, but not much in shape. They are good for holding prey but are not adapted for cutting or grinding. Therefore, crocodilians usually swallow their prey whole or tear off large chunks that are thrown backward toward the throat and are swallowed principally due to gravity. To dismember its prey, a crocodilian has to take a firm hold and then spin its body to separate the piece held in its mouth. This process depends on inertia and is more effective for large prey and large crocodilians. Dismemberment of prey is uncommon in small crocodilians.

The conical teeth are effective for holding prey but suffer severe stress during biting and when the crocodilian spins, and they are frequently broken or pulled out. Fortunately for the predator, crocodilian teeth that are lost during feeding are soon replaced by another that grows up from the same tooth socket.

Crocodilians have the strongest stomach acids of any group of vertebrates, so they can digest

most animal matter, including bones. Nevertheless, assimilation efficiency is probably greater for food types similar to that of the bodies of crocodilians, such as vertebrate muscle, than for other material, such as invertebrate chitin. Most invertebrates are also small, so that it may not be worthwhile for larger crocodilians to hunt them. The ontogenetic shift in diet is probably the most studied aspect of food habits in crocodilians and the pattern is similar in almost all species.

African crocodiles (*Crocodylus niloticus*) up to about half a meter long eat mainly insects and spiders. Individuals between 2 and 4 m eat mainly fish and snails, and animals over 4 m eat mainly mammals, but also some reptiles and fish (Cott 1961). A similar pattern is seen in all species of crocodilians, but some change the types of prey at smaller sizes, and some never make the transition to eating mainly mammals.

There are probably several reasons that small crocodilians eat mainly insects and spiders. The first is that these are probably the most common prey within the size range that they can swallow. However, capturing terrestrial vertebrates probably requires stealth and understanding of the surrounding habitat. Recently hatched crocodilians usually form crèches that are accompanied by their mother for the first few weeks or up to 2 years in some cases. Soon after, the juveniles start to disperse, probably egged on in their movements by territorial adults for the decade or more they take to get to breeding size. During that time, they may not remain in any one area long enough to develop a useful hunting map.

Large juveniles and sub adults usually eat mainly crustaceans, mollusks, and fish, the proportions depending on availability within the habitats the species occupies. Although even large crocodilians will occasionally take insects or other invertebrates, the energetic contribution of these groups tends to be negligible, and it is unlikely that large crocodilians actively seek these prey types unless they occur in unusually large concentrations.

The largest crocodilians often eat a large proportion of mammals, and these probably represent the most digestible food packets available. However, they are also often hard to catch and come

close to water infrequently. Therefore, the strategies that crocodilians use to catch them are likely to be different from those used to catch widely distributed prey, such as insects, or prey that occurs in predictable places, such as fish.

Differences among size classes in the type of prey eaten depend to a certain extent on the seasonal differences in habitats. In places with large inundated floodplains, such as flooded savannas and forests, and hence large seasonal differences in access to different habitats, diets tend to differ less between size classes, because all must move with the advancing flood waters. In habitats with less seasonal variation, such as rivers and lakes, different size classes tend to segregate in different habitats and differences are more pronounced.

The species with the greatest divergence from the usual size-related changes in diet is Schneider's dwarf caiman, *Paleosuchus trigonatus*. It lives in dense Amazonian rainforest with little primary productivity in the understory. Therefore, insects and mollusks tend to be less abundant and individuals less than a meter long eat many frogs, snakes, and other small vertebrates. Fish, which tend to be scarce in the small streams are never found in abundance in its diet and the diminutive adults, which rarely reach two meters long, eat many mammals, including pacas, porcupines, and monkeys. As porcupines and monkeys rarely descend to the edge of the stream, it is hard to imagine what strategy this species uses to capture them. They must be very successful, as they maintain higher biomass than all the mammalian carnivores together in the same type of habitat.

It is often claimed that snout-shape in crocodilians reflects their diet, fish-eating species having long, thin snouts, and species that take large prey, such as ungulates, having heavier, wider snouts. However, this is only partially true. Species that live in open-water habitats tend to have thinner snouts, but they are not any longer in relation to body length. It makes sense to have a thin snout, which causes less resistance, if you live in open water, whether you eat fish or not. Fish just happen to be the nutritionally most valuable prey in open-water habitats.

The species of crocodilians that eat the most large ungulates and other large mammals, the

estuarine crocodile, *Crocodylus porosus*, and the Nile crocodile, have snouts of intermediate width, which can be considered a generalized form for crocodilians. This form of snout appears to be adequate to withstand the stresses of capturing large prey in relation to the size of the crocodilian.

The species of crocodilians with the widest snouts, including extinct forms, do not feed on the largest prey, but all live or lived in densely vegetated habitats, such as marshes, so it seems that extreme widening of the snout is an adaptation to smashing through thick vegetation rather than protection against breakage while pulling down large prey.

## Conclusion

In summary, we know quite a bit about the morphological and physiological adaptations of crocodilians associated with feeding and digestion, but because of their nocturnal cryptic habits we know little about the cognitive and behavioral adaptations that have lead them to be the most successful and persistent nonflying Archosaurs.

## Definition

Movement used by crocodilians (true crocodiles, alligators, caimans, gharials, and false gharials) to traverse terrestrial and aquatic environments.

The Crocodilians are quadrupedal archosaurs closely related to living birds. Currently, the crocodilians are divided into five major groups: true crocodiles, alligators, caimans, gharials, and false gharials (Hutchinson et al. 2019). Alligators and caimans are known for their blunt heads, crocodiles for their elongated heads, and gharials and false gharials for their narrow heads (Buffetaut 1979).

Crocodilians live in warm environments inhabiting fresh and/or salt bodies of water. They range from semi-aquatic to almost fully aquatic. Although morphological differences exist between species regarding head shape, locomotor patterns appear to largely similar across the group. The crocodilians are capable of different gait patterns ranging from walking, running, galloping, and swimming. It is important to recognize that extant crocodilians are more adept at swimming compared to their locomotor efforts on land. Much of the locomotor capabilities of these species have evolved in response to improved predatory capabilities and to escape predation themselves.

## Terrestrial Locomotion

Terrestrial gaits of crocodilians include walking, running, and galloping. Walking can be further broken down into sprawling (or belly-dragging) and high-walking, and are almost always symmetrical (when footfalls of the forelimb and hindlimb are evenly spaced in time) lateral-sequence (each hindlimb footfall is followed by an ipsilateral forelimb footfall) diagonal-couplets (contralateral forelimbs and hindlimbs travel together) (Fig. 1). This footfall sequence is inherently stable due to a high proportion of the stride being spent as either diagonal bipods (two contralateral limbs in contact with substratum) and large tripods (three widely splayed limbs in contact with substratum), both of which create a line of support under the midline of the body (Granatosky 2018; Hildebrand 1976, 1989). Compared to mammals and birds, the crocodilians demonstrate low locomotor cycle rhythmicity (Granatosky et al. 2020).

Belly-dragging, characterized by a sprawled posture (limbs held lateral to body), is used for slow speed movement in muddy terrains. Some evidence suggests that crocodilians adopt belly-dragging due to its low energy expenditure

**Crocodilia Locomotion, Fig. 1** “Hildebrand” plot displaying phase against hindlimb duty factor collected during quadrupedal walking in crocodilians ( $n =$  four species)

(Pashchenko 2018; Reilly and Elias 1998). High-walking is a mode of transport that uses a semi-erect posture, a posture between erect (limbs directly under body) and sprawling (limbs held lateral to body) (Reilly and Elias 1998). Alligators primarily use this high-walking posture during normal walking gaits, while crocodiles may stand more erect to navigate rough terrain (e.g., leaving water, climbing over trees, brush, and hills). During high-walking hindlimb stance phase, the hip and knee are extended, causing the body to roll over the opposite foot (Gatesy 1991; Reilly and Elias 1998; Willey et al. 2004). The medial rotation in the hip may allow for a purer sagittal plane motion (flexion/extension). As the limb retracts, the ankle plantarflexes (raising the posterior aspect of the foot off the ground). The force of plantar flexion aids the knee and hip in extension, lengthening the limb. Prior to foot-off (initiation of swing phase), the hip and knee begin to flex, allowing the propulsive force to move the limb forward. Swing phase begins with rapid dorsiflexion to lift the limb off the ground. The hip gradually extends until foot down occurs for the next stance phase. In the forelimb, forelimb excursion is mediated by the shoulder, elbow, and wrist joints and by the shoulder girdle (Gatesy 1991; Reilly and Elias 1998; Willey et al. 2004; Baier and Gatesy 2013). Lateral bending of the shoulder girdle creates greater stride length in the forelimb.

Stance phase of belly-dragging and high walking differ in hindlimb joint angles. Femoral angles of both belly-dragging and high walking remain relatively static during the stance phase; however, the femur is more protracted and abducted during sprawling, while the knee and ankle joints have more pronounced flexion (Reilly and Elias 1998; Gatesy 1991). During swing phase femoral adduction of both postures decreases slightly, but maximum adduction is achieved again immediately prior to foot down. Knee extension increases during swing phase in both postures. In belly-dragging, maximum extension is achieved well before foot down as to maintain close contact with the substrate. Knee extension continues until immediately before foot down in high-walking to maximize stride length.

High-walking alligators raise a portion of their tails off the ground but still drag a significant amount of weight (~20% of body mass), thus shifting their center of mass caudally towards the hindlimbs (Willey et al. 2004). The forelimbs provide significantly less propulsion during high-walking compared to the hindlimb, but provide a means of braking and support (Willey et al. 2004; Gatesy 1991; Baier and Gatesy 2013). Variation in limb-loading is quite high between cycles in crocodilians (Granatosky et al. 2020), which may explain increased limb bone safety factors in crocodiles compared to mammals and birds (Blob et al. 2014).

Galloping in crocodilians has been observed in several true crocodile species, such as *Crocodylus johnstoni*, *C. porosus*, and *C. niloticus*. The gallop is most often initiated from a resting position, but sometimes can be developed from the high-walk when there is a need for increasing speed. Likely, galloping behavior evolved in crocodilians as a means of rapid escape. However, such movement also allows the animals to leap or bound over obstructions such as logs and rocks (Webb and Gans 1982). Galloping in crocodilians is highly variable, and animals have been recorded using a

transverse or rotary gallop, a half-bound or a bound (Renous et al. 2002; Zug 1974). There are four different types of gallops observed in *C. johnstoni*. Type 1 corresponds to a bound with a flight, with a short lead time separating the synchronized footfalls of the forelimbs from the synchronized footfalls of the hind limbs. A Type 1 gallop is observed in about 7.5% of the crocodiles. A Type 2 gallop, seen in 31.8% of crocodiles, is a three stroke gallop, deemed, half-bound with unsynchronized forelimbs, but synchronized hindlimbs. A Type 3 gallop is a rotary gallop with leading fore- and hindlimbs on opposite sides, seen in 21% of the crocodilians. Type 4 gallop, which was most frequently observed (39.5%), is the transverse gallop with leading fore- and hindlimbs on the same side of the body (Fig. 2). All four types of asymmetrical gaits have speeds between 1 and 1.40 ms<sup>-1</sup>. However, the Type 1 bounding gait has a speed greater than 2 ms<sup>-1</sup>. Among these gaits, rotary gallop offers a higher level of maneuverability, while the transverse gallop demonstrates a higher level of stability (Renous et al. 2002). This diversity of asymmetrical gaits in *C. johnstoni* is not overly surprising considering patterns of rhythmicity in

**Crocodylia Locomotion, Fig. 2** Foot fall diagram representing the two types of gallops observed in crocodiles. LH = left hindlimb; LF = left forelimb; RH = right hindlimb; RF = right forelimb

bradymetabolic (poikilothermic) tetrapod lineages (Granatosky et al. 2020).

Crocodilian kinematic patterns change dramatically during galloping. During the gallop, the back arches vertically and the straight tail moves up and down. Such back movements are of note, as axial kinematics switch from the plesiomorphic condition of lateral undulation to a derived dorso-ventral undulatory motion (Hutchinson et al. 2019). When a crocodilian begins to gallop, the initial bound is done by raising the anterior body on the front legs while the hindlimbs quickly unfold, lifting the acetabulum, so thus the femur becomes vertical and the tibia horizontal. When the hindlimbs unfold, the forelimbs swing outward and tilt under the trunk. The end of the initial bound is marked when the forelimbs contact the substrate. The angle between the humeral and radio-ulnar portions decreases because the forelimbs begin to slightly bend and rotate. Momentum continues to move the trunk forward. Following the initial unfolding of the hindlimbs, they are folded once again and swung outward and anteriorly before being unfolded again. The hindlimbs are fully extended when they contact the substrate (Webb and Gans 1982).

## Swimming and Diving

Aquatic locomotion is essential for the crocodilians, as many species rely on their aquatic habitats for prey, reproduction, and social interactions (Seebacher et al. 2003). Accordingly, the crocodilians have evolved several anatomical features that allow for quick and maneuverable aquatic movements. Webbing between the toes provides surface area, aiding in positioning in the water and controlling speed of movement and performing turns. While swimming, the limbs are pressed against the body, reducing hydrodynamic drag thus contributing to speed. The tail is the greatest contributor to propulsion during swimming. Relative to the body, the limbs of the crocodilians are small; however, the tail is quite large and muscular. The lateral shape of the crocodilian tail increases surface area, allowing for axial propulsion in water. The tail moves in a sinusoidal or

s-shaped fashion. During steady swimming, velocity is dependent on an increase in tail beat amplitude (Seebacher et al. 2003).

The crocodilians are also capable of diving. Diving allows the crocodilians to submerge underwater for periods of time ranging from minutes to hours. The digestion of stones contributes to the dive capacity. Stone digestion has been found to increase specific gravity thus prompting the crocodilians to increase their lung volume and storage of pulmonary oxygen. This increased lung volume allows crocodilians to remain still underwater near the ground for extended periods of time without continually surfacing for air. The presence of these digested stones, or gastroliths, is positively correlated with the duration of a crocodilian dive (Uriona et al. 2019).

## The “Death Roll”

The death roll is a rapid rotation along the longitudinal axis of the crocodilian’s body. The rotational effort, or spinning, begins when the fore- and hindlimbs are pressed against the body and the head and tail are in line with the body’s axis. The crocodilian then bends into a C-shape with its limbs still pressed against its body. The ability to centralize the crocodilian mass by keeping the legs close to the body creates a powerful and fast spin by reducing drag. Upon initiating the spin, the body remains straight while the head and tail rotate around their own longitudinal axes. The end of the spin consists of the head, body, and tail straightening out and the legs abducting from the body yielding the sprawled posture. During the spin, the head, body, and tail all spin with the same direction and angular speed (Fish et al. 2007). The speed and force created by this behavior is a powerful tool to engage and dismember prey once in the animal’s jaws. The death roll is also observed during the need to escape conflict or to injure a competitor (Drumheller et al. 2019).

To better understand the forces at play in the death roll it is important to note the presence of the *roll axis*. The roll axis is parallel to the body of the crocodilian and runs from the snout to approximately near the base of the tail (Fish et al. 2007).

While the C-shape taken by the crocodilians at the beginning of the spin allows each body part to possess its own vector of angular momentum they eventually all cancel out yielding an angular momentum of zero. When the crocodilian engages the roll axis during a spin, only a tenth of the revolution around the roll axis is completed. The minor motion on the roll axis does not contribute to the angular momentum of the spin. The lack of net change in angular momentum due to the orientation of the crocodilian yields a reduced inertia and increased spin rate (Fish et al. 2007).

## Conclusion

Traditional depictions characterize crocodilian movement as slow and lumbering, but these animals are capable of a diverse range of locomotor behaviors, such as walking, running, galloping, swimming, diving, and death rolling. Walking can be broken down into belly-dragging and high-walking, each with distinct gait kinematics. Galloping provides the crocodilians a quick means to escape and traverse obstacles, and represents one of the few examples of asymmetrical locomotion in a non-mammalian tetrapod. In the water, the crocodilians are impressive swimmers that separate the functional roles of the limbs for maneuverability and the tail for propulsion. Crocodilian locomotor behavior also highlights the fact that these animals are not “mindless lizards,” but are able to utilize rocks from their environment to increase the duration of dive time. Finally, the crocodilians can use their remarkable strength to death roll that assists in prey manipulation and defense.

## Definition

Crocodylia – the clade comprised of the last common ancestor of *Gavialis gangeticus*, *Alligator mississippiensis*, and *Crocodylus niloticus* and all of its descendants (Brochu 2003)

## Introduction

Living crocodylians are some of the most remarkable reptiles on the planet, inhabiting the tropical and subtropical regions of the world where they are important faunal elements of their respective ecosystems. Currently, there are 26 accepted extant species (however, the actual number may be greater, with other potential species awaiting recognition; e.g., Grigg and Kirshner 2015) classified into three families: Alligatoridae (which includes the genus *Alligator* and the caimans of the genera *Caiman*, *Melanosuchus*, and *Paleosuchus*), Crocodylidae (which includes the genera *Crocodylus*, *Mecistops*, and *Osteolaemus*), and Gavialidae (which includes the genus *Gavialis*). The genus *Tomistoma*, today represented by a single species, has a contentious taxonomic placement, as molecular studies find it closely related to *Gavialis* (e.g., Willis et al. 2007), while most morphological studies consider it as related to crocodylids (e.g., Piras et al. 2010). Collectively, they are all part of the clade *Crocodylia*, which itself is a part of the suborder *Eusuchia* within a highly diverse group – the

Crocodylomorpha – that has had a long evolutionary history spanning from the Late Triassic or over 200 million years. This article will briefly cover the morphology of living crocodylians. For more detailed discussions on the subject, the reader is referred to the literature cited herein.

## General Appearance

The crocodylian body is characterized by a large head with a prominent rostrum (snout), a short neck, a relatively long and widened trunk, and a long, laterally compressed muscular tail that is essential for swimming (Fig. 1). To an extent, the general form of crocodylians superficially resembles that of lizards, despite the fact that they are not lizards themselves nor are they closely related to lizards. The closest living relatives of crocodylians are the birds, and together they are the only surviving representatives of the Archosauria, a clade that also includes the non-avian (non-bird) dinosaurs, pterosaurs, and other extinct forms. Upon hatching, crocodylians start their lives as very small. As adults, crocodylians are large reptiles, with the estuarine or saltwater crocodile (*Crocodylus porosus*) being known by individuals to exceed 6 m in total length and weighing over a ton; the smallest taxa (like the dwarf crocodiles of the genus *Osteolaemus*, dwarf caimans of the genus *Paleosuchus* and the Chinese alligator *Alligator sinensis*) grow around 2 m in total length (Grigg and Kirshner 2015).

The rostral shapes and proportions differ between taxa and range from the extremely elongated and thin rostra of Indian gharials (*Gavialis gangeticus*) to the short and broad rostra of the aptly named broad-snouted caiman (*Caiman*

*latirostris*). Therefore, based on rostral proportions, crocodylians can be generally categorized into three non-monophyletic groups: longirostrine or “long snouted,” mesorostrine or “middle snouted,” and brevirostrine or “short snouted” (Grigg and Kirshner 2015; Fig. 2). Importantly, this categorization by rostral shape is not necessarily indicative of close taxonomic relationships; for example, the Australian freshwater crocodile (*Crocodylus johnstoni*) is of the longirostrine morphotype, thus more similar in that regard to the distantly related Indian gharial than to the closely related brevirostrine mugger crocodile (*Crocodylus palustris*).

Crocodylians have relatively short limbs, with the hind limbs usually larger than the front. There are five toes in the forefeet and four in the hind feet (the fifth toes of the hind feet are rudimentary bones), with only the first three toes in both fore- and hind feet bearing claws (Fig. 3). The feet are webbed, with the degree of webbing being commonly more pronounced in the hind feet, while some species lack forefeet webbing.

Crocodylians are sexually dimorphic (meaning there are physical differences between males and females other than their sex organs; read below), with the males typically growing larger than the females. Among all living crocodylians, Indian gharials are the most sexually dimorphic. Mature male Indian gharials possess a ghara, which is a bulbous soft tissue surrounding the nostrils that is absent in females. Apart from size, distinguishing the sex in other species is challenging, and one of the most reliable ways to do so is to inspect the sex organ inside the cloaca. The cloacal orifice is a ventral slit-like opening slightly posterior to the hind limbs, and inside it are hidden the penis (if male) or clitoris (if female).

### Eyes and Ears

The eyes of living crocodylians are positioned on top of their heads, such that when most of their bodies are submerged, the eyes (along with the nostrils and ears) can be subtly exposed above water, allowing the animals to observe the surrounding surface for potential prey or danger. There are two eyelids, an upper and lower, which close the eyes. Also, crocodylians have nictitating membranes, which are semitransparent tissue sheets that cover and protect the eyes when underwater, effectively acting as third eyelids. The nictitating membranes are located at the anterior corners of the eyes and stretch backward when engaged. The pupils are slit-like and

vertical, widening at night (or at low light levels) and narrowing during the day (or at high light levels). Eye color is variable among species, ranging from shades of green, brown, yellow, and black (Grigg and Kirshner 2015). Crocodylians possess a light-sensitive reflective surface at the back of the eye known as a tapetum lucidum, enhancing night vision and causing eyeshine glow when artificially illuminated at night.

The ears are located behind the eyes, with the external auditory meatus (ear opening) opened to a slit only anteriorly when the crocodylian is not submerged (Fig. 4a). The posterior portion of the meatus is almost always closed, regardless if the animal is under- or above-water. When the animal is underwater, the meatus is entirely closed. The external auditory meatus is covered dorsally by a large superior earlid/earflap and anteroventrally by a smaller inferior earlid/earflap (Shute and Bellairs 1955; Grigg and Kirshner 2015). The ear can be divided into the outer, middle, and inner ear (Richardson et al. 2002; Grigg and Kirshner 2015). The outer ear is the portion between the earflaps and the tympanic membrane (eardrum). Within the middle ear (or tympanic cavity) is a very small and thin bone called the columella, which transmits sounds from the tympanic membrane to the inner ear. The pneumatized (air-filled) middle ear cavity connects to the pharynx via complex tympanopharyngeal (often called Eustachian) tubes that may serve in pressure regulation (Young and Bierman 2019). The

inner ear contains the semicircular canals, the otolith organs (utricle, sacculus, and lagena), and the cochlea (Grigg and Kirshner 2015).

### Skin

The crocodylian skin is composed of non-overlapping keratinous scales (scutes), with some body regions having osteoderms embedded underneath (read below; Fig. 5). The skin on the

face/head is tightly attached to the skull. The scales across the body are of different sizes, with the finer ones typically found around the neck and flank regions, whereas the larger are on the limbs, belly, and tail. Enlarged scales around the pectoral (chest) region are referred to as a ventral collar. The tail has large, rectangular scales present on its lateral sides, while dorsally, the tail bears two subparallel rows of upright triangular scales (double crest whorls) that converge toward the middle or slightly posterior and continue as a single row (single crest whorls) to the tip (Brazaitis 1973). Some species have smaller yet conspicuous keel-like scutes on the posterior edges of the extremities as well. Scalation patterns are usually similar within a single species (although exceptions are known, e.g., Augustine et al. 2018) but variable between different species (Brazaitis 1973).

The coloration is different across taxa (Brazaitis 1973; Grigg and Kirshner 2015) but can also differ between individuals of the same species and is dependent on the habitat the crocodylian lives in. The jaws and underside of the body are commonly lighter in color than the dorsum, flanks, and head, yet the underside tends to be darker in smaller taxa like the dwarf caimans and dwarf crocodiles (Grigg and Kirshner 2015). In some species, darker spots, blotches, and/or bands may be present on the lower jaws, backs, bellies, flanks, limbs, and tail. Skin color and patterns change ontogenetically (during growth) as well, such as in American alligators (*Alligator*

**Crocodylia Morphology, Fig. 4** Australian freshwater crocodile (*Crocodylus johnstoni*) (a) close-up of the head. The subhorizontal slit behind the eye is the ear opening. Notice the interlocking upper and lower jaw teeth (b) gaping. The gular flap in b is indicated with an arrow. (Photographs by Jorgo Ristevski)

**Crocodylia Morphology, Fig. 5** Taxidermy mount of an estuarine crocodile (*Crocodylus porosus*), dorsal scutes pattern (a) on the back and (b) neck region

*mississippiensis*) where young individuals have vibrant yellow bands over most of their bodies that disappear with maturity. Some crocodylians are able to change their skin color depending on the lighting of the environment they live in (Grigg and Kirshner 2015 and references therein; Merchant et al. 2018; Staniewicz et al. 2018). Captive *Crocodylus* individuals placed in black containment tanks were observed to change to dark shades across the dorsum and flanks, while those contained in white tanks became lighter in these corresponding regions (Grigg and Kirshner 2015; Merchant et al. 2018). Transferring individuals to alternate tanks was also associated with a corresponding color change to match the new surroundings (ventral surfaces remained unchanged across all instances). Other crocodylids (dwarf crocodiles of the genus *Osteolaemus* and slender-snouted crocodiles of the genus *Mecistops*) did not exhibit significant color change (or no change), whereas alligatorids usually did not change their skin colors at all (Merchant et al. 2018). Indian gharials and Sunda gharials (*Tomistoma schlegelii*) displayed an opposite trend to that observed in *Crocodylus*, i.e., darker conditions caused skin lightening, and lighter conditions caused skin darkening (Merchant et al. 2018); the same effect was observed in wild Sunda gharials; however, it appears that younger individuals are more capable to change color than larger adult Sunda gharials (Staniewicz et al. 2018). As indicated in the performed experiments, the change in color was triggered by visual stimulation (individuals placed in white tanks that had their eyes covered adopted dark colors; individuals placed in well-illuminated black tanks adopted light colors; Merchant et al. 2018), and temperature was not a determining factor (Merchant et al. 2018; Staniewicz et al. 2018). Aberrantly colored forms such as melanistic (meaning with darker colors) and leucistic (almost entirely white in color) are known, although melanistic forms occur more frequently than the leucistic (Richardson et al. 2002; Grigg and Kirshner 2015). Albinistic individuals are also known, which similarly to the leucistic have white skin. Albinistic individuals can be distinguished from

the leucistic by the presence of pink eyes, whereas leucistic individuals have normally colored eyes (Grigg and Kirshner 2015). Present on the skin scales are very small and black dome-like structures called integumentary sensory organs, or ISOs for short, also referred to as dome pressure receptors (DPRs) by some (e.g., Soares 2002). All living crocodylians have ISOs on their heads, jaws, and body scales, except for alligatorids which lack ISOs on their bodies. Usually, there is only one ISO per body scale; however, the ISO density is greater on the head, particularly on the snout where more than one ISO may be present on each scale. On top of the cranial table, there may be few ISOs or none (Grigg and Kirshner 2015). The functional significance of the ISOs is not fully understood yet; however, they seem to be mechanoreceptors that enable crocodylians to sense and respond to surrounding stimuli, like sensing movement underwater, during feeding, and are possibly important during courtship, among other behaviors (e.g., Soares 2002; Leitch and Catania 2012; Grigg and Kirshner 2015).

Three types of exocrine glands are present in the skin of crocodylians: mandibular (lower jaw) glands found at the posterior ventral angles of the jaws; paracloacal glands found in the lateral cloacal walls of the proctodaeum; and small glands embedded under the scales on the dorsal surface of the body (Grigg and Kirshner 2015). The mandibular and paracloacal glands secrete oily substances that may in part function as pheromones, although their full purpose is still unclear (Grigg and Kirshner 2015).

## Osteology

The following osteological description is based primarily on the estuarine crocodile, supplemented with comments on other crocodylian species.

### Skull and Mandibles

The dorsal surface of the skull (Fig. 6a) is sculptured with pits, grooves, and ridges. Sculpturing is also present on the external (in this case equivalent to the lateral and ventral) mandibular surfaces, albeit to a smaller extent than on the skull.

**Crocodylia Morphology, Fig. 6** Estuarine crocodile (*Crocodylus porosus*) skull in (a) dorsal, (b) ventral (or palatal), and (c) left lateral view

The degree of sculpturing is variable between individuals, getting more pronounced through ontogeny. The alveolar margins on the rostrum bear numerous small openings called neurovascular foramina. The anterior part of the rostrum is formed by the premaxillae. Located dorsally on the premaxillae is the large opening for the nostrils called the external naris. Another opening on the premaxillae, smaller than the external naris, is the so-called incisive foramen. The largest bones of the rostrum are the maxillae. Dorsomedially, the maxillae are separated from each other but are in

sutural contact ventrally where they contribute significantly to the secondary bony palate. The maxillae (as well as the dentaries; read below) of many species have a concavo-convex, undulating lateral profile, which is referable as festooned. Festooning is either faint or completely absent in the longirostrine taxa (Fig. 4a). The nasals are long and relatively narrow bones that are placed dorsomedially on the rostrum and reach the external naris posteriorly, where they send a short process within it. In alligators and dwarf crocodiles, the nasals are much more extensive anteriorly and

together with the premaxillae form an internarial bar (Iordansky 1973; Fig. 2). Contributing to the anterior orbital margins are the lacrimals. Some crocodile species, like the estuarine crocodile, have pronounced lacrimal ridges that stretch from the anterior margins of the orbits and forward on the rostrum. The prefrontal bones comprise the anteromedial margins of the orbits, and ventrally they send robust vertical processes called the prefrontal pillars which contact the palatines. The frontal is a large element, constituting the majority of the medial orbital margins. Anteriorly, the frontal forms an elongated pointed process that is wedged between the prefrontals and nasals. The orbits are the openings on the skull that house the eyes. Plate-like bones, called palpebrals, are situated at the medial margins of the orbits that among living species are especially prominent in the dwarf crocodiles and dwarf caimans, capping the eyes dorsally (Fig. 7).

Medially, the orbits are separated from each other by the cartilaginous interorbital septum. Dorsally between the orbits, caimans of the genera *Caiman* and *Melanosuchus* have distinctive transverse ridges. The cranial table (the portion of the skull above and posterior to the eyes) is comprised of the postorbitals, squamosals, parietal, and most of the frontal, and, in some cases, there may be a small contribution by the supraoccipital. The posteromedial part of the cranial table is formed by the parietal, which is another relatively large element.

The postorbitals form the anterolateral portions of the cranial table. Ventrally, the postorbitals send descending, pillar-like processes that form significant portions of the postorbital bars. However, in addition to the postorbitals, the postorbital bars are also formed by the ascending processes of the jugals ventrolaterally and by the ectopterygoids ventromedially. The squamosals make up the posterolateral parts of the cranial table. On their lateral surfaces, the postorbitals and squamosals bear horizontal grooves for attachment of the upper earlids. The two large openings dorsally on the cranial table are the supratemporal fenestrae. The size of the supratemporal fenestrae can range across taxa, with estuarine crocodiles having fenestrae of a smaller circumference than their orbits, but some crocodylians, such as Indian gharials, have very large supratemporal fenestrae (Fig. 2). In dwarf caimans, the supratemporal fenestrae usually close with ontogeny (Brochu 1999). The laterotemporal fenestrae are the trapezoid-like openings on the posterolateral parts of the skull, separated from the orbits by the postorbital bars. On the posterior walls of the supratemporal fossae are two small openings, called the temporal canals (or temporo-orbital foramina). The jugals are elongated bones that form the majority of the ventral margins of both the orbits and laterotemporal fenestrae. The quadratojugals are located at the posterolateral portions of the skull, contacting the jugals

#### Crocodilia Morphology,

**Fig. 7** Juvenile American alligator (*Alligator mississippiensis*) skull, periorbital region (meaning around the orbits), with the right palpebral indicated

anteriorly and anterolaterally, and quadrates medially. The quadratojugals contribute to the laterotemporal fenestrae's posterior margins and within them send spine-like processes termed the quadratojugal spines. The quadrates are large, unsculptured bones found at the posterolateral parts of the skull. The distal or posterior portions of the quadrates bear the quadrate hemicondyles that articulate with the mandibles. Ventrally, the quadrates bear several crests, termed crests A, B, and D, which serve as attachments for muscle tendons; the degree of development for these crests is variable among individuals, with larger and older crocodylians commonly having more developed crests (Iordansky 1973). Additional types of quadrate crests are found in different species, but not all crests are present in a single species (Iordansky 1973). Posteromedially on each quadrate, near the medial quadrate hemicondyle is the foramen aëreum. Another opening, this time on the occipital surface (back of the skull; Fig. 8), is the cranioquadrate passage, opened between the quadrate and the paroccipital process of the exoccipital on each side.

The opening between the quadrate and squamosal is the external auditory meatus (otic aperture). Anterior to the external auditory meatus is the conspicuous subtympenic foramen; however, this foramen can vary in size in some taxa. The

external auditory meatus and subtympenic foramen are just some of the elements of the meatal chamber complex, for which an excellent review is given by Montefeltro et al. (2016). The palatines are located ventrally on the skull (Fig. 6b), and their dorsal surfaces together with those of the pterygoids form the nasopharyngeal duct. The large oval openings ventrally on the skull are the suborbital fenestrae. The pterygoids are large, wing-like elements that contact the palatines anteriorly and ectopterygoids laterally. Mature Indian gharial males have massive swollen structures dorsally on their pterygoids called pterygoid bullae (Iordansky 1973). Posteromedially on the pterygoids are the secondary choanae. One of the defining features of the Eusuchia, the clade to which all living crocodylians belong to, is secondary choanae that are fully enclosed by the pterygoids, and another feature is the presence of procoelous vertebrae (Salisbury and Frey 2001; Brochu 2003; read below). The ectopterygoids are robust bones that contact the maxillae and jugals dorsally and the pterygoids posteroventrally. Other bones of the palate are the vomers; however, in most species, these are not exposed externally at adulthood, except in the black caiman (*Melanosuchus niger*) where the vomers are situated between the premaxillae and maxillae, and

**Crocodylia Morphology, Fig. 8** Estuarine crocodile (*Crocodylus porosus*) skull in occipital view

in the Sunda gharial, where the vomers are situated between the maxillae and palatines (Iordansky 1973). The laterosphenoids compose the anterolateral parts of the braincase walls. Dorsal to the medial contact of the laterosphenoids is a large opening for the olfactory tract of the brain. Still at the medial contact of the laterosphenoids and ventral to the opening for the olfactory tract is the opening for the optic nerves, and ventrolateral to the former are the openings for the oculomotor nerves. Small foramina for the trochlear nerves also pierce the laterosphenoids. Laterally on the braincase walls are the large trigeminal foramina (openings for the trigeminal nerves, also called foramina ovals). The prootics are bones of the braincase that have small external exposure and may be difficult to observe on an articulated skull. The prootics bound the trigeminal foramina posteriorly and contact the laterosphenoids anteriorly, while the quadrates cover the prootics medially (see Holliday and Witmer 2009 for more details on laterosphenoids and surrounding structures). Dorsomedially on the occipital surface of the skull is the supraoccipital. The supraoccipital may have small exposure on the dorsal surface, wedged medially into the parietal. Set between the supraoccipital and exoccipitals ventrally and parietal and squamosals dorsally are narrow openings called the posttemporal fenestrae. The exoccipitals are one of the largest bones on the occipital surface, and laterally, they develop the paroccipital processes. Anteromedially, the exoccipitals, along with the supraoccipital and prootics, form the tympanic bullae, which house the inner ear; the tympanic bullae are visible through the foramen magnum (Iordansky 1973). The foramen magnum is the large opening at the center of the occiput. Lateral to the foramen magnum and occipital condyle, the exoccipital bears the hypoglossal foramina, the foramina vagi, and the posterior carotid foramina. The basioccipital is located medioventrally on the occiput and forms the semispherical occipital condyle. Ventral to the basioccipital on the occiput, there is a small exposure of the basisphenoid. Ventrally, posterior to the secondary choanae and between the basioccipital and basisphenoid is the foramen of

the median pharyngeal tube (following Dufeu and Witmer 2015 and Young and Bierman 2019; this opening is often referred as the median Eustachian foramen), while laterally to the aforementioned are the smaller pharyngotympanic foramina (following Young and Bierman 2019; these openings are often referred as the lateral Eustachian foramina). The basisphenoid has additional exposure posterolaterally on the braincase walls, posterodorsal to the pterygoids, and posteroventral to the quadrates (Fig. 6c); furthermore, the basisphenoid forms a mediolaterally narrow and dorsoventrally expanded sheet of the bone at the anterior portion of the braincase, called the basisphenoid rostrum, dorsomedial to the pterygoids and ventromedial to the laterosphenoids. The basisphenoid rostrum supports the abovementioned interorbital septum. The cranial cavities are pneumatized, and possess paratympanic air sinuses with their related diverticula (Dufeu and Witmer 2015).

The largest bones of the mandibles (Fig. 9) are the dentaries. The mandibular symphysis is the joint that connects the dentaries anteromedially. In disarticulated mandibles, the anteromedial portion reveals the rugose symphyseal plate (Fig. 9b). Posteromedial to the symphysis is an anterior exposure of the Meckelian groove, and within it is housed the Meckel's cartilage. Most of the Meckelian grooves are covered laterally by the splenials, which are long and smooth elements on the medial mandibular surfaces. The posterodorsal portions of the mandibles are formed by the surangular bones, while the angulars form the posteroventral. Together with the posterior portions of the dentaries, the anterior of the surangulars and angulars surround the external mandibular fenestrae, the largest openings of the mandibles. The external mandibular fenestrae can vary in size between different species. Attached medially on both the surangulars and angulars are the articulars. Anteriorly on the articulars are the concave fossae (glenoid fossae) that articulate with the hemicondyles of the quadrates. Medially on the articulars are the mandibular foramina aërea. Additionally, the articulars develop the long retroarticular processes that project posterodorsally. The smallest bones of the mandibles

**Crocodylia Morphology, Fig. 9** Estuarine crocodile (*Crocodylus porosus*) mandibles in (a) dorsal, (b) right mandible in medial, and (c) left mandible in lateral view

are the coronoids. Anteroventrally to the coronoids and posteriorly to the splenials are the small middle intermandibular foramina. Other medial openings are present in the mandibles,

these ones situated more ventrally, between the dentaries and angulars, called the caudal intermandibular foramina. Trough-like concavities on the posteromedial mandibular portions

serving as muscle attachment for the mandibular adductor muscles are the mandibular adductor fossae (Iordansky 1973).

### Dentition

The teeth of the upper jaw are set in the premaxillae and maxillae, while all teeth of the lower jaw are set in the dentaries. The number of teeth is variable among taxa, with the Indian gharial having the highest number among living crocodylians, usually between 104 and 110 in total (Iordansky 1973). The tooth count can also vary intraspecifically (among different individuals of the same species), sometimes due to ontogeny, but in some cases even individuals of the same age may differ in their tooth counts. Estuarine crocodiles bear five teeth in the premaxillae, with the fourth tooth being the largest and the second smallest. Between the first and second premaxillary teeth are two deep pits that receive the first dentary teeth during jaw occlusion (jaw closure) which may perforate the premaxillae anteriorly if they grow sufficiently large. Additional reception pits for dentary teeth are present between the third and fourth and fourth and fifth premaxillary alveoli, but these are usually not as deep as the anterior-most pits. Similarly shallow pits are present between some maxillary alveoli as well. Posterolaterally, at the sutural contact between the premaxilla and maxilla, crocodiles have a notch that fits the fourth dentary tooth when the jaws are occluded. This notch is absent in alligators. In crocodylids, the largest maxillary tooth is the fifth, while in alligatorids it is the fourth. The size of the largest maxillary tooth causes a swelling on the dorsal surface of the maxilla, more pronounced in larger individuals. Estuarine crocodiles have 14 teeth in each maxilla and 15 teeth in each dentary; thus, estuarine crocodiles have 68 teeth in total (a slightly variable number when keeping in mind individual variation). In order to more conveniently express the number of teeth in a crocodylian, dental formulae may be used. Taking the above specified tooth count, the dental formula for an estuarine crocodile would be  $5 + 14/15$  (i.e., 5 teeth in each premaxilla +14 teeth in each maxilla/15 teeth in each dentary). If the tooth count is slightly variable, the dental

formula could instead be, for example,  $4(5) + 13-14/15$  (i.e., 4 or 5 teeth in each premaxilla +13 to 14 teeth in each maxilla/15 teeth in each dentary). Dental formulae for other species can be found in Iordansky (1973). Crocodiles and gharials have interlocking dentition, meaning when their jaws are closed, the teeth from the lower jaws are still visible and interlock with those of the upper jaws (Fig. 4a). On the other hand, alligatorids have an overbite, that is, when their jaws are closed only, the teeth from the upper jaws are visible for the most part. Crocodylian teeth are set in sockets, or alveoli, a condition referred to as thecodont. In juveniles, the teeth at the posterior of the jaws are set in grooves instead of an individual alveolus, a condition referred to as aulacodont; however, with ontogeny each tooth will eventually be enclosed in an individual alveolus, thus becoming thecodont (Bertin et al. 2018). Within its alveolus, the tooth is attached by a non-mineralized ligament, and this type of attachment is called gomphosis (Bertin et al. 2018). The teeth of living crocodylians have conical crowns and subcylindrical hollow roots (Fig. 10). In estuarine crocodiles, the external crown surfaces (covered by an enamel layer) are faintly ornamented with a fluted pattern, and the mesial (a dental term equivalent to anterior) and distal (in context of dentition, a term equivalent to posterior) sides of the teeth bear ridges called carinae.

The crown is delimited from the root by a short transitional surface called the cervix dentis (cervix in brief) or the neck of the tooth (Hendrickx et al. 2015). Crocodylians, like many other reptiles, are polyphyodont, meaning they continually shed and replace their teeth throughout life. Once fully formed, the roots start to be resorbed gradually as part of the replacement cycle. The fully grown functional tooth is accompanied by a small, bud-like replacement tooth, initially situated lingually (toward the side of the tongue, as opposed to labially, or toward the outside of the jaws) inside the alveolus that continues to grow within the (now gradually resorbing) hollow root, eventually positioning itself right underneath the functional tooth (Bertin et al. 2018). Once the old tooth is shed, the replacement tooth takes the exact same position within the alveolus.

The morphology of crocodylian teeth is generally uniform but does vary slightly. For example, alligators, caimans, and dwarf crocodiles have blunter and almost button-like posterior teeth (molariforms or pseudomolars) that are used in crushing hard-shelled prey (e.g., gastropods, turtles), while the comparatively longer and sharper anterior teeth (caniniforms or pseudocanines) are employed for seizing prey, combat, and display

(Erickson et al. 2012; Fig. 11). Due to this subtle differentiation in size and shape, crocodylian dentition can be regarded as pseudoheterodont, as opposed to truly heterodont dentition as found in mammals, where in the latter, different types of teeth exist such as incisors, canines, premolars, and molars. In longirostrine crocodylians, the teeth tend to be less differentiated in both shape and size.

### Postcranial Skeleton

The postcranial skeleton (Figs. 12, 13, 14, and 15) is comprised of the vertebral column with the ribs (parts of the axial skeleton) and the limbs with the limb girdles (appendicular skeleton).

The vertebral column can be divided into cervical (neck), dorsal (subdivided into thoracic or the dorsal vertebrae that bear ribs, and lumbar, or the last three to five dorsal vertebrae that lack ribs), sacral, and caudal (tail) vertebrae (Fig. 12). The number of vertebrae is similar across all living crocodylians and usually comprises 9 cervical, 15 dorsal, 2 sacral, and depending on the species between 35 and 45 caudal (Brochu 1996; Grigg and Kirshner 2015). As mentioned above, the vertebrae of eusuchians are procoelous. In a procoelous vertebra, the centrum (vertebral body) is concave anteriorly, while posteriorly there is a semi-spheroidal convex condyle that articulates with the concave anterior (i.e., vertebral fossa) of the succeeding vertebra (Salisbury and Frey 2001; Fig. 13). All vertebrae in living crocodylians are procoelous, except for the atlas, second sacral, and first caudal vertebra. The first cervical vertebra comprises the atlas-proatlas complex which

**Crocodylia Morphology, Fig. 11** Juvenile American alligator (*Alligator mississippiensis*) skull, close-up of the jaws in right lateral view. Notice the molariform at the posterior and caniniform teeth at the anterior of the jaws

articulates with the occipital condyle of the skull and has a distinct morphology from the other vertebrae (Fig. 13a). The second sacral vertebra is biconcave, by having concave anterior and posterior ends, thus lacking the posterior semi-spheroidal condyle. The posterior articular condyle on the first sacral vertebra is weakly

developed. The first caudal vertebra is biconvex, by having semi-spheroidal convex condyles both anteriorly and posteriorly (Salisbury and Frey 2001; Fig. 13f). The second cervical vertebra is called the axis, and anteriorly it bears the odontoid process which articulates with the atlas (Fig. 13a). Attached dorsally on the centrum of a typical

vertebra is the neural arch, and between the centrum-neural arch contact is the neurocentral suture (Fig. 13d). The neurocentral sutures close, becoming invisible during ontogeny, with the caudal neurocentral sutures being closed upon hatching, and the cervical neurocentral sutures close last, at maturity (Brochu 1996). The neural arch is joined to the centrum via the neural arch peduncles, and the opening between the peduncles is called the neural canal (or vertebral foramen; Salisbury and Frey 2001), through which the spinal cord passes. The tall and mediolaterally thin dorsal projection on the neural arch is the neural spine. In addition to the semi-spheroidal articulation, the vertebrae also articulate by the prezygapophyses and postzygapophyses of the neural arch, where the postzygapophyses of the preceding vertebra overlay/connect to the prezygapophyses on the succeeding one. Also, anteroventrally on the centra of all cervical (except the atlas) and first three or four thoracic vertebrae are

short and thin processes called hypapophyses. Projecting laterally from the neural arches of the cervical and first two thoracic vertebrae are the diapophyseal processes, and projecting laterally from the centra of the same are the parapophyseal processes. The articular surface of the diapophyseal process (called the diapophysis) and the articular surface of the parapophyseal process (called the parapophysis) articulate with its associated rib (Fig. 13b; read below). Projecting laterally from both sides of the thoracic vertebrae neural arches are the transverse processes, which articulate with the thoracic ribs (Fig. 13c, d). Transverse processes are present in the lumbar vertebrae as well, although as stated above, these do not articulate with ribs. According to de Souza (2018), the transverse processes are a result of the merging between the diapophyseal and parapophyseal processes. The transverse processes on the sacral and caudal vertebrae are only weakly developed. The two sacral vertebrae have

**Crocodilia Morphology, Fig. 15** A selection of isolated osteoderms from an Australian freshwater crocodile (*Crocodylus johnstoni*)

sacral ribs, which are unlike the other ribs by being robust and having expanded lateral-most portions that articulate with the ilia of the pelvic girdle (Fig. 13e). The caudal vertebrae bear caudal ribs that look remarkably similar to the transverse processes of dorsal vertebrae (Fig. 13f). The ribs of the sacral and caudal vertebrae are attached to their respective neural arches and centra, specifically to the lateral articular regions called synapophyses, which are formed by the merging of the diapophyses and parapophyses (de Souza 2018). Attached posteroventrally on most caudal vertebrae are the hemal arches. In females the first hemal arch is absent, while their second is reduced

in size. Posteriorly, toward the tip of the tail region, the caudal vertebrae gradually decrease their dorsoventral heights and lose their caudal ribs and neural spines, yet their centra become more elongated, and the posterior convex condyles are also getting less prominent, until the small and elongated centra are all that remain of the last caudal vertebrae.

All cervical, thoracic, sacral, and anterior caudal vertebrae have ribs attached to them. The cervical ribs are rather short, whereas the thoracic ribs are long and slender. An exception among the cervical vertebrae are the ribs that attach to the atlas (atlantal ribs) and axis (axial ribs), which are

longer than the other cervical ribs (Fig. 13a). As described above, the ribs of the sacral and caudal vertebrae are distinct, and the following description applies to the cervical and thoracic ribs. The proximal portions of these ribs articulate with the vertebrae by two process, the capitulum and tuberculum (Fig. 13b). The tuberculum articulates with the diapophysis and the capitulum with the parapophysis. The thoracic ribs consist of three segments, which are the vertebrocostal, intercostal, and sternocostal (Richardson et al. 2002; Grigg and Kirshner 2015). Ventrally, or on their bellies, crocodylians also possess gastral (stomach) ribs or gastralia that are spread from the pectoral girdle anteriorly to the pelvic girdle posteriorly. Compared to the cervical and thoracic ribs, the gastralia are slenderer.

Located ventrally on the throat are the paired hyoid bones, which are thin, long, and curved, somewhat superficially resembling ribs.

The limb girdle associated with the forelimbs is called the pectoral girdle, whereas the limb girdle associated with the hind limbs is the pelvic girdle (Fig. 14). The pectoral girdle is represented by the scapulae, coracoids, and interclavicle. The scapula and coracoid (Fig. 14b) are in contact with each other, and at their lateral contact is the glenoid, a socket for articulation of the proximal portion (epiphysis) of the humerus. Situated ventromedially between the distal portions of the coracoids and amidst the sternal cartilage is the elongated interclavicle. From proximal to distal, the forelimb bones include the humeri, radii and ulnae, carpals (wrist bones), metacarpals, phalanges (forefoot or manual digit bones; the same term applies to the hind foot or pedal digit bones), and unguals (distal-most/terminal phalangeal bones that support the claws). The largest bone of the forelimb is the humerus, and on each humerus is a bony flange called the deltopectoral crest, which serves as a muscle attachment site. Distally, the humerus articulates with the radius and ulna. The distal ends of the ulna and radius articulate with the carpal bones ulnare and radiale, respectively; the carpal bones articulate distally with the metacarpals and the metacarpals with the manual phalanges. The ilia, pubes, and ischia form the pelvic girdle (Fig. 14c). The ilium is a relatively robust

bone that is in contact with the ischium, and together they form the acetabulum in which the proximal femoral head articulates. The ischium has two well-developed peduncles, an anterior and posterior that contact the anterior and posterior peduncles of the ilium. The pubis contacts only the ischium, which excludes the pubis from contacting the ilium. From proximal to distal, the hind limb bones include the femora, tibiae and fibulae, tarsals (ankle bones), metatarsals, phalanges, and unguals. The femur (thigh bone) is a long, sigmoid-like bone that bears a knob called the fourth trochanter which is a place for muscle attachment. The femur articulates with the tibia and fibula, and distally to the latter are the tarsal bones astragalus, calcaneum, and the distal tarsals. The tarsal bones articulate with the metatarsals. There are only four well-developed pedal phalanges.

### Osteoderms

The osteoderms are the bony plates embedded under the crocodylian's skin (Figs. 5 and 15), most prominently concentrated on the dorsal surface, with additional coverage on the flanks, limbs, and tail. The osteoderm covering serves as a shield among other functions, and the degree and pattern of osteodermal covering varies from species to species, which is useful for species identification. For example, estuarine crocodiles lack post-occipital osteoderms or the osteoderms found just posterior to the cranial table and anterior to the nuchal (neck) osteoderms (Fig. 5b). The osteodermal covering is greater in the smaller taxa, such as the dwarf crocodiles, dwarf caimans, and the Chinese alligator (Grigg and Kirshner 2015). The osteoderms can range in size and shape depending where they are located on the body (but are also variable interspecifically or between different species), and like the sculpturing on the skull, they too have pits and grooves on their dorsal surfaces, whereas ventrally they are smooth. The dorsal surface of an osteoderm has small vascular foramina, and dorsomedially there is usually a longitudinal keel. The osteoderms on the dorsal surface of the trunk are neatly arranged in six anteroposteriorly oriented and parallel rows (Richardson et al. 2002).

## Musculature

Crocodylians are strongly built animals with accordingly developed musculature. Although they lack muscles for facial expression, the masticatory muscles at the back of the cranium that insert in the mandibles are well developed. Thanks to their powerful jaw musculature, crocodylians can exert tremendous bite forces that are the strongest among living animals (Erickson et al. 2012). The jaws can be closed shut with great speed, and opening them forcefully can be very difficult. The major jaw muscles are the mandibular depressor (*M. depressor mandibulae*), external mandibular adductor (*M. adductor mandibulae externus*), posterior mandibular adductor (*M. adductor mandibulae posterior*), dorsal (anterior) pterygoid (*M. pterygoideus dorsalis*), ventral (posterior) pterygoid (*M. pterygoideus ventralis*), and pseudotemporal (*M. pseudotemporalis*) and intramandibular (*M. intramandibularis*) muscles. A comprehensive review and descriptions of the craniomandibular muscles in the broad-snouted caiman, including their origination and insertion points, can be found in Bona and Desojo (2011). Posterocranially, the axial, or trunk musculature, can be divided into two groups: epaxial, or the muscles lying dorsal to the transverse processes of the vertebrae and the ribs, and ventral to the dorsal osteoderms; and hypaxial, or the muscles ventral to the transverse processes of the vertebrae that make up the lateral and abdominal walls of the body. The epaxial musculature is comprised out of four groups, which from medial to lateral are the *spinalis* (made out of the *articulo spinalis*, *spinalis*, and *multifidus*), *tendinoarticularis*, *longissimus dorsi*, and *iliocostalis*; the hypaxial musculature includes the external oblique, internal oblique, and transverse abdominal muscles (Salisbury and Frey 2001; Grigg and Kirshner 2015). Ventrally or on the belly are the large *rectus abdominis* muscles. The chest region is ventrally covered by the large *pectoralis* muscle which inserts at the deltopectoral crest of the humerus. As the tail is used to propel the crocodylian when swimming, it has especially developed musculature. The dorsal caudal musculature includes the

*tendinoarticularis* muscle group medially and more laterally is the *longissimus caudalis*. Ventrally on the tail are the large *caudofemoralis* muscles (made of the smaller *caudofemoralis brevis* and larger *caudofemoralis longus*), and lateral to the *caudofemoralis* are the *ilioischio caudalis* muscles. Numerous muscles compose the appendicular musculature that originate and insert at the limbs and limb girdles. Detailed descriptions of crocodylian musculature can also be found in Chiasson (1962), Richardson et al. (2002), and Grigg and Kirshner (2015 and references therein), with Klinkhamer et al. (2017) focusing on the appendicular musculature of the estuarine crocodile.

## Digestive System

At its anterior, the digestive system begins with the oral cavity (mouth) that contains numerous teeth and the tongue. The tongue is affixed ventrally on the mouth and is largely (but not entirely) immobile. The tongue's surface is covered by taste buds. At the back of the throat is the gular valve, formed primarily by the gular flap ventrally, palatal flap dorsally along with smaller lateral wraps that can be engaged in order to prevent water from entering the stomach and lungs while active underwater, such as when subduing prey (Grigg and Kirshner 2015; Fig. 4b). Crocodylids possess salt glands on their tongues that aid them in excreting salt, making them adept at venturing in saline waters (Grigg and Kirshner 2015 and references therein). Salt-excreting glands are absent in alligatorids, and consequently they are more seldomly found in salt water compared to crocodylids (Brochu 2003; Grigg and Kirshner 2015). Lingual (meaning of the tongue) salt glands are also recognized in Sunda and Indian gharials; however, currently there is limited data on the salt-excreting capacity of these two species (Grigg and Kirshner 2015). Crocodylians do not masticate (chew) and instead swallow their food whole. Should the food item be larger than they can swallow, crocodylians can crush it with their posterior teeth, shake it, thrash it around, or engage in a "death roll" in order to rip it apart

into smaller chunks. Then, the crocodylian lifts and repositions its head slightly so as to plunge the food item to the mouth's posterior and into the pharynx – this technique is known as inertial feeding and is mostly implemented with the head above-water or on land (Grigg and Kirshner 2015). From the pharynx continues the long, tube-like esophagus that connects to the stomach. The stomach can be divided into four regions, with the cardia being on the left anterior portion of the stomach connecting with the esophagus, the fundus, the corpus or the largest part of the stomach, and the pylorus, which is found on the right posterior of the stomach sac and is the exit from the stomach to the small intestine, specifically the duodenum (Richardson et al. 2002; Romão et al. 2011). The small intestine is composed of the duodenum, jejunum, and ileum, with the latter segment connecting to the colon or large intestine (Romão et al. 2011). The colon connects to the cloaca. The pancreas is an organ located close to the duodenum and produces digestive enzymes as well as hormones (Richardson et al. 2002). The liver is a large, conical organ that is formed of a right and left lobe, with the right lobe being the larger of the two (Richardson et al. 2002; Romão et al. 2011).

## Respiratory and Cardiovascular Systems

Externally, the respiratory system begins anteriorly with the nostrils, which in crocodylians are located anterodorsally on the rostrum, near the tip. The nostrils are set on a slightly raised pad called a nasal disk and are controlled by the dilator muscles to open and constrictor muscles to close them (Richardson et al. 2002; Grigg and Kirshner 2015). Thus, when a crocodylian is underwater, the nostrils are fully closed, and when relaxed on land, the nostrils tend to be loosely opened (Grigg and Kirshner 2015). The relatively long nasal cavity is separated from the oral by the secondary bony palate formed by the premaxillary, maxillary, palatine, and pterygoid bones. The nasal cavity is relatively long and contains pneumatized paranasal air sinuses with related diverticula (Witmer 1997). The nasal cavity opens into the

nasopharyngeal duct which in turn opens through the secondary choanae posteriorly. Lying on the back of the throat is the glottis, a slit-like opening that connects to the larynx. The larynx then leads to the lungs via the long, tub-like trachea. Toward the posterior and near the heart, the trachea branches off into the left and right bronchi, which are short tubes that connect to the lungs. The black caiman has an unusually wide trachea anteriorly that narrows near the bronchi (Grigg and Kirshner 2015). The two lung sacs are highly vascularized and non-lobulated, each being oval in shape (Chiasson 1962; Richardson et al. 2002).

The majority of extant reptiles have three-chambered hearts, comprised of two atria and one ventricle that are only partially divided by an incomplete interventricular septum. However, crocodylians deviate from this norm by being the only living reptiles to possess a four-chambered heart – two atria (a left and right) and two ventricles (a left and right) divided by an interventricular septum – which in that regard makes crocodylians more similar to mammals and birds. Unique to the hearts of crocodylians is a small opening called the foramen of Panizza (named in honor of the Italian anatomist Bartolomeo Panizza, who published the first study describing this foramen), located within the semilunar valve between the left and right aortas. The right aorta is the main artery that supplies blood from the heart to the body. Another interesting feature of crocodylian hearts are the “cogwheel valves,” which are teethlike nodules arranged in a semicircle and located at the base of the pulmonary arch within the subpulmonary conus that lead from the right ventricle to the pulmonary aorta (Grigg and Kirshner 2015).

## Urogenital System

The two kidneys are elongated, with highly lobulated ventral surfaces, and lie ventral to the lumbar vertebrae (Chiasson 1962; Richardson et al. 2002; Grigg and Kirshner 2015). Posteriorly from each kidney stretches a short and narrow tube, the ureter, that leads to the cloaca. The cloaca is the

terminal passage for the digestive, reproductive, and urinary systems, with defecation and urination (as well as egg laying in females) going through it (Romão et al. 2011). The cloaca can be subdivided into three chambers, with the coprodaeum at the anterior (where the feces is formed), urodaeum in the middle (where urine is stored, as crocodylians do not have bladders), and proctodaeum at the posterior (Grigg and Kirshner 2015).

In males, the paired testes have an oval shape and are attached to the dorsal body cavity and located between and anterior to the kidneys (Grigg and Kirshner). The testes are smaller in immature males, with sexually mature individuals having enlarged testes during breeding seasons (Richardson et al. 2002). Posterodorsally on each testis is the epididymis, from which continues a narrow tube called the vas deferens that transports sperm to the penis. The penis sits within the proctodaeum and has no role in urination (Grigg and Kirshner 2015).

In females, the paired ovaries are located ventromedially and anterior to the kidneys. The ovaries in sexually immature females contain small ovarian follicles (spherical cellular structures) that become larger in sexually mature, breeding females. Leading from each ovary to the cloaca is an oviduct, a membranous, irregularly shaped tubelike structure through which the eggs pass. Following the summation by Grigg and Kirshner (2015), there are seven sections of the paired oviducts, which are the anterior and posterior infundibulum, the uterine tube, the uterotubular junction, the anterior and posterior uterus, and the vagina. Females also have a clitoris hidden within the proctodaeum of the cloaca, situated in a similar position as the male's penis, although the clitoris is smaller in comparison (Grigg and Kirshner 2015).

## Brain and Nervous System

The brain (Fig. 16) is housed in the braincase or endocranial cavity of the skull. The outer surface of the brain is rather smooth and covered by external membranes called meninges, while internally the brain has fluid-filled ventricles (Romer

1956). The brain can be divided into three major sections: the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain). The main subdivisions of the prosencephalon are the telencephalon and diencephalon, while the metencephalon and myelencephalon are the main subdivisions of the rhombencephalon.

Starting with the forebrain, the telencephalon includes the bulbous olfactory lobes (or olfactory bulbs) that connect to the relatively large cerebral hemispheres by the elongated olfactory tracts. The posterior portion of the prosencephalon is the diencephalon, and ventrally on it is the infundibulum, whose posterior end supports the pituitary gland (or hypophysis). The optic nerves are crossed anterior to the infundibulum, at the optic chiasma. The mesencephalon's major portion are the optic lobes (optic tectum). The metencephalon is largely consisted of the lobe-like cerebellum dorsally (with the auricles forming laterally from it) and part of the medulla oblongata. The myelencephalon is the posterior, or distal-most portion of the brain, and includes the rest of the medulla oblongata which exits through the foramen magnum and continues as the spinal cord. From the brain offshoot 12 cranial nerves, which serve important sensory and motor functions and exit through several foramina on the skull. In order, these are the olfactory (cranial nerve I), optic (cranial nerve II), oculomotor (cranial nerve III), trochlear (cranial nerve IV), trigeminal (cranial nerve V), abducens (cranial nerve VI), facial (cranial nerve VII), acoustic (cranial nerve VIII), glossopharyngeal (cranial nerve IX), vagus (cranial nerve X), accessory (cranial nerve XI), and hypoglossal (cranial nerve XII) nerves. The trigeminal nerve is the largest and branches off into the ophthalmic, maxillary, and mandibular divisions. Cranial nerves I and II originate from the prosencephalon, nerves III and IV from the mesencephalon, while nerves V–XII originate from the rhombencephalon. As mentioned above, the spinal cord extends from the medulla oblongata and runs through the neural canals of the vertebral column, almost to the tip of the tail (Richardson et al. 2002). Numerous nerves are present on the spinal cord that innervate the postcranium, with each spinal nerve branching off into

**Crocodylia Morphology, Fig. 16** Brain model of an American alligator (*Alligator mississippiensis*) in (a) dorsal, (b) left lateral, and (c) ventral view. The Roman numerals denote the cranial nerve roots. (After Romer (1956))

a dorsal and ventral ramus, innervating the epaxial and hypaxial regions, respectively. The complex network of nerves (termed a plexus) that innervate the forelimbs is the brachial plexus, and the network innervating the hind limbs and tail is the lumbosacral plexus (Romer 1956; Chiasson 1962; Richardson et al. 2002).

## Definition

Sensory modalities that allow crocodilians to interact with the world.

## Introduction

Crocodilians have captured the imagination of scientists and the general public for decades. This is partially explained by their morphology and lore of being ancient hunters. Their habitat is diverse, from open waters in lakes and rivers to marshes and swamps to even beaches and the ocean. The main connecting thread among all these niches is the semiaquatic nature of their lifestyles. Aside from living and foraging in the water, crocodilians come to land to thermoregulate and rest. Typically crocodilians are endemic

to areas around the equator, with exceptions of the American and Chinese alligators, whose ranges extend as far north as the south-eastern of the United States and the Yangtze River in central China. Crocodilians also prefer the lowlands, with rare exceptions. No crocodilian permanently resides in the ocean, although in Australia some animals will swim in it. Several species tolerate brackish water of mangrove swamps and estuaries. Habitat use has been shown to be different among crocodilians (Lang 1987). The American alligator, for example, prefers habitats with open water, which have considerable floating vegetation, to dry ground and cover. Furthermore, inland alligator densities are usually lower than coastal populations, suggesting a possible preference to either open areas or brackish water. Crocodilians are diverse in their preferred habitat, with some somewhat more terrestrial, choosing edges of lakes, swamps, and ponds, where access to basking areas is easier. Others spend more time in the water and inhabit rivers and estuaries. The Asian gaviel, for example, feeds on fish and lives in the waters of swift rivers. Comparatively, the Chinese alligator prefers the slow moving waters of the Chinese floodplains. Such distribution is sensitive to seasonality and during the dry season; caimans stay in deep pools, while in the flooding season they scatter. One unique population of crocodiles in the southern edge of Africa's Sahara live in caves and burrows, and under rocks near bodies of water that dry up and disappear for months (Wilson 1987).

## Review of Crocodilians

The order Crocodylia is subdivided into three families: the Crocodylidae, in which all crocodiles are grouped; the Alligatoridae, where alligators and caiman are found; and the Gavialidae, formed by true and false garhials. There are currently 23 species of crocodilians identified. A large majority of species live in tropical regions, but the American alligator and the Chinese alligator are able to tolerate colder climates and are found in highest latitudes. The family Alligatoridae (alligators and caimans) are segregated to the

Americas, with the exception of the Chinese alligator which is endemic to eastern China. Also in the Americas are few species of crocodiles (Crocodylidae) even though most species are found in Africa, Asia, and to a certain extent in India. Indian gharials are the only species of Gavialidae and are present in that region.

## Sensory Neurobiology Intro

The physical characteristics of a habitat influence the evolution of sensory structures (Schellart 1992). A semiaquatic habitat creates a unique set of sensory challenges for crocodilians, and these animals have to detect the environment both in water and on land. The association between habitat and sensory morphology has been examined in many species of vertebrates showing a high diversity of sensory solutions (Farris 2015). Crocodilians have been shown to rely mostly on their senses of vision, audition, and mechanosensation (Fig. 1), although some modalities remain to be investigated: magnetoreception and electroreception.

## Vision

Not many studies have examined the visual system of crocodilians, but of the few, all show that the visual system of crocodilians is well adapted

to land use. This is supported by the fact that their eyes are severely defocused underwater (Fleishman et al. 1988). The spatial resolving power and spectral sensitivity of the saltwater (*C. porosus*) and freshwater (*C. johnstoni*) crocodile have been recently studied by Nagloo and colleagues (2016). In these animals, the fovea is organized in a streaked nasotemporal pattern to increase high spatial acuity. There are five photoreceptor types, with three single cones and twin cone and a rod. The single cones are violet, green, and red, suggesting trichromatic vision. The twin cones have the same maximum absorption as the red sensitive cones. The peak spatial resolving power for this fovea, for both crocodilians, is around 8 cycles/degrees.

## Hearing

Crocodilians have, relatively consistent across species, excellent hearing. Their sensitivity is focused on middle tones, declines for lower tone, and quickly becomes insensitive at higher frequencies (above 3 kHz; Fig. 2a; e.g., Wever 1971; Higgs et al. 2002). Crocodilian auditory sensitivity is affected by temperature; in *Caiman*, the best sensitivity for auditory fibers moves to higher frequencies with higher temperatures (Smolders and Klinke 1984). Though hearing is most sensitive on land, a smaller but similar range

## Crocodilian Sensory Systems,

**Fig. 1** Crocodilian sensory receptor organs.

Crocodilians transduce olfactory cues via their nares, visual cues via their eyes, auditory cues via ears, and mechanosensory cues via dome pressure receptors

**Crocodilian Sensory Systems, Fig. 2** American Alligator auditory sensitivity and tympanic membrane. (a) Audiogram, generated using an auditory brainstem response recordings, shows the frequency sensitivity of

alligator hearing. (b) Tympanic membrane with attached columella dissected from juvenile specimen. Scale bar, 0.25 cm (Figures were adapted from Bierman and Carr 2015)

of sensitivity and some localization abilities have been measured in alligators with their ears submerged (Higgs et al. 2002; Dinets 2013). Vocal communication is important for maternal care and promoting group cohesiveness among the young (reviewed by Vergne et al. 2009).

Crocodilian ears are located on either side of the head caudal to the eyes. The tympanic membrane is protected by inferior and superior earlids. In air, the earlid muscle is relaxed and the earlid is slightly open (e.g., Vergne et al. 2009). Sound waves can stimulate the tympanic membrane on the external side, and also on the internal side, by traveling through canals within the animal's head. These internal pathways help the animal determine the location of sound cues (Bierman et al. 2014). Like birds, vibrations of the tympanic membrane are transmitted to the inner ear via a single ossicle, called a columella (Fig. 2b). Also like birds, the inner ear cochlear duct, which contains the hearing and vestibular organ, is short and crooked (e.g., Vergne et al. 2009). The hearing organ consists of a basilar papilla, basilar membrane, and tectoral membrane. On the basilar papilla, there are two types of sensory hair cells, tall and short, arranged in a tonotopic manner (birds also have tonotopy, but in a gradient of hair cell sizes; Gleich et al. 2004). Tall and short hair cells vary in the number of afferent fibers with which they connect the ear to higher brain structures.

## Vestibular

Along with hearing, the inner ear of vertebrates also contain vestibular organs, important for postural, reflex, and locomotor activities. Crocodilian vestibular organs, like in all gnathostomes, include two otolith organs, the utricle and saccule, and three toroidal semicircular ducts. Hair cells found in the otolith organs sense gravitational and other linear acceleration, while hair cells in the semicircular ducts sense rotational movements in three planes. The complexity of this multiorgan sensory system allows for morphological and functional variation, allowing specialization related to, “specific sensory demands imposed by an organism’s behavior, including the specifics of locomotor function” (Georgi and Sipla 2008; Sipla and Spoor 2008). Among crocodiles, differences in vestibular organ morphology are associated with the degree of aquaticity. Most crocodilians are considered semiaquatic and some vestibular organ difference are seen between these and gharial, which are highly aquatic, and a fossilized fully terrestrial basal crocodylmorph (Georgi and Sipla 2008).

## Mechanosensation

Crocodilians have various sensory organs on their skins that are responsible for the sense of touch.

Naked nerve endings, Pacinian corpuscles and Merkel cells, are present in the dermis of crocodilians. One unique specialization found across the body of crocodilians and on the heads of alligators are the dome pressure receptors (DPRs; Soares 2004). These specialized sensory organs are composed of a cluster of cells that lie in the interface of the epidermis and the keratin layer. A large nerve bundle innervates the medial part of DPRs, and in alligators, they give rise to the trigeminal nerve. This nerve is large and composed of numerous branches that travel through fenestra in the skull. DPRs are sensitive to water ripples, although it is unclear to what physical property of the water motion they are tuned. Crocodilians are stalking predators and sit on the interface of the air and water waiting for prey to appear. DPRs are able to detect disturbances that arise from prey entering or leaving the water. Another possible sensory role for DPRs is communication. Throughout the year, but particularly during the breeding season, alligators bellow to declare territory and locate suitable mates (Garrick and Herzog, 1978). Both males and females will bellow to attract mates and declare territory by sucking air into their lungs and blowing it out in intermittent, deep-toned roars (Vliet 1989). Bellowing is performed in a head-up, tail-arched posture, so the lungs are immediately underwater. Low-frequency waves from a bellowing alligator can cause the surface of the water directly over and to either side of its back to appear to “boil” in what is commonly called the “water dance” (Lang 1976; Vliet 1987). Large bellowing choruses of alligators can occur (Garrick and Lang 1977). It is unclear if DPRs are involved in communication during bellowing, but due to the nature of the stimulus, it is likely that these organs are involved.

## Osmosensation

The ability to detect different levels of salinity is advantageous for species that inhabit coastal or estuarine habitats. These animals have to cope with fluctuating osmolality by either osmoconforming or osmoregulating. Jackson

and Brooks (2007) showed that dome pressure receptors are also sensitive to osmotic pressure. Osmoreceptors sense the osmolality of a solution by expanding or shrinking in response to changes in the osmotic environment. Changes in environmental osmolality cause water to flow across cell membranes and equilibrate the osmolality of the cytoplasm. By changing cell volume and intracellular ionic strength, large changes in environmental osmolality can affect the physical state of cells and tissues. In this study, Jackson and Brooks (2007) found that when postcranial dome receptors in crocodylids are blocked, animals lose the ability to discern salinity levels. These sensory organs, which are located on the scales, also flatten when exposed to higher osmotic pressure. This is a novel and interesting role for dome sensory receptors.

## Chemosensation

Chemoreception in semiaquatic animals has to detect volatile and water-soluble compounds in both environments, but little is known about how crocodilians use their olfactory system. Neill (1971) reported that the American alligator detects blood in the water. Weldon et al. (1990) conducted behavioral and olfactometer experiments which showed that crocodilians detect both air-borne and water-soluble chemicals and use their olfactory system for hunting. When above water, crocodilians enhance their ability to detect volatile odorants by gular pumping, a rhythmic movement of the floor of the pharynx (Gans and Clark 1976; Putterill and Soley 2006). The nasal cavity of the American alligator contains two different chemosensory systems incorporated in the same sensory epithelium: the olfactory system proper and solitary chemosensory cells (Hansen 2007). Nothing is known how these two systems integrate chemosensory information.

## Electroreception and Magnetoreception

Electroreception is particularly useful for navigating, orienting, and detecting prey in low-light

conditions, such as at night or in deep, murky water. However, there is no evidence that any crocodilian has electroreceptors. Several species of vertebrates are known to orient themselves using the Earth's magnetic field, through magnetoreception (Lohmann and Johnsen 2000; Wiltshko and Wiltshko 2005). But to our knowledge, no studies to date have demonstrated that crocodilians can self-orient to magnetic fields.

## Conclusion

Although crocodilians have inhabited the imagination of scientists for numerous years, basic information about its sensory biology is still elusive. Clearly, they rely on vision, audition, and mechanosensation for interactions with the environment, but other sensory modalities still remain to be investigated.

Department of Philosophy, Lund University,  
Lund, Sweden

## Introduction

Crocodylians (crocodiles, alligators, caimans, and gharials) are arguably the most cognitively complex living nonavian reptiles. They display a rich

behavioral repertoire in a variety of contexts, such as hunting, spatial orientation, and social interactions, including communication in several modalities. Their forebrain is the largest among nonavian reptiles and they are the only order with structures resembling a cerebral cortex (Grigg and Kirshner 2015). Crocodylians are a monophyletic taxon, more closely related to birds than lepidosaurs (lizards and snakes). Studies on avian cognition have become highly prevalent in recent decades. Some birds possess complex cognitive abilities comparable to primates and other mammals, although the reptilian (including birds) and mammalian lineages split approximately 320 million years ago. Therefore, one approach to understanding the evolution of these capacities is to study the cognition of nonavian reptiles (Wilkinson and Huber 2012). Crocodylians play an important role in this endeavor due to their key phylogenetic position between birds and other amniotes. They act as a bridge between their archosaur cousins (birds) and the accumulating knowledge of cognition in lepidosaurs and chelonians (tortoises and turtles). Crocodylians also share a common ancestor with all dinosaurs, including the recent birds. Therefore, studying crocodylian cognition allows us to learn more about the lives of extinct dinosaurs, one of the evolutionarily most successful tetrapod groups.

Cognition is understudied in crocodylians. Most of our knowledge about their abilities to process information is inferred from observations and not from controlled experimental studies. In this chapter, we discuss most of the empirical literature on crocodylians in detail to showcase the many gaps which still need to be filled. We also describe various aspects of crocodylian behavior, which provide an initial level of insight into their abilities and could serve as promising starting points to develop experimental setups for future research.

## Learning

Most studies on learning capacities in crocodylians date back to the middle of the last

century. An excellent overview of this literature was provided by Burghardt (1977) and an update by Sazbo et al. (2019).

Most of the older studies are concerned with variations of the reversal learning paradigm, usually conducted in a T-maze and with the objective to avoid an aversive stimulus (heat and electric shock). For instance, small American alligator (*Alligator mississippiensis*) juveniles were placed in an arena with a heat lamp above it and two adjacent arms led to areas with cool-water pools. After establishing which arm (left or right) was preferably used by a subject to escape the heat, its preferred route was blocked with a piece of plexiglass. The alligators learned to act against their initial preference and reduced the time it took them to reach the pool over consecutive trials (Davidson Jr 1966). In a comparable experiment, spectacled caimans (*Caiman crocodilus*) learned to inhibit their initial turning preference (Northcutt and Heath 1971). The maze had a single choice point, one direction leading to a dead end and the other to a ramp to the caimans' home pen. Similar to the alligators, the caimans had to counteract their side preference, but they were not exposed to excessive heat and the results were scored as correct or incorrect choices of direction and not the time to reach the home pen. The one-year-old subjects significantly reduced the percentage of errors over five sessions. Another study used the T-maze to test which cues, spatial or visual, spectacled caimans primarily use to escape electric shock (Williams Jr 1967). The caimans had one choice point where one arm led to a trap, the other to an enclosure with a pool. Additionally, visual cues were provided with the walls of the arms having either a white or a black sheet metal panel attached to them. Seven of eight subjects learned to associate a side and a color with the goal enclosure. In the test, there was a goal enclosure at either end of the maze and for each subject, the colors on the walls were reversed. All subjects went in the same direction as in the training and did not follow the wall colors. Thus, spatial cues appear to be more salient than visual ones in spectacled caiman. In a follow-up study (Williams Jr and Robertson 1970), two groups of caiman had different training

procedures. One group learned first to associate the correct direction again by spatial and visual cues. After reaching the criterion, the correct direction was only indicated by the visual cue and could be on either side. The other group was only trained with the visual cue from the beginning. The group with visual and spatial cues reached criterion significantly quicker than the group with visual cues only. When the group with visual and spatial training had to solve the problem by the colors alone, it took them longer to reach criterion than in the previous condition. This was strong evidence that spatial cues are indeed more important. However, there probably was an effect of the training in the group with both cues, because the total number of trials in both phases (visual and spatial, and visual only) was lower than the number of trials it took the "visual cue only group" to reach criterion. While this difference was not significant, it suggests that the group with both cues did not have to learn the visual-only condition from scratch. Crocodylians are clearly sensitive to spatial cues (also see the "Spatial Cognition" section). However, in all these studies the goal was a location, an area of safety with water. It can be argued that to accurately test the importance of visual and spatial cues, the goal should have been a conceptually unrelated entity. This could have been a food reward, as crocodylians are predators and therefore unlikely to expect to find food always in the same location. Crocodylians can indeed learn to discriminate between a range of different colors as was shown in an earlier experiment using food rewards (Nickel 1960). This study ultimately had only one subject, a juvenile broad-snouted caiman (*Caiman latirostris*), but it at least serves as a proof of concept.

In a further study with the T-maze setup, spectacled caimans seemed to adopt a maximizing strategy in a probability learning task (Williams and Albinia 1972). Either side could be rewarded but with unequal probability (e.g. a side could be reinforced in 30% of the trials). Caimans reduced their proportion of choices of a side with a decreasing probability of that side being rewarded. Their performance was more similar to turtles and rats than to birds in

contemporary studies (Burghardt 1977; Williams and Albiniak 1972).

Another study employed a serial reversal learning paradigm and utilized food rewards to test learning abilities in American alligators and American crocodiles (*Crocodylus acutus*) (Gossette and Hombach 1969). The animals were trained to press against blocks on either side of an apparatus to reveal an opening through which they could receive a food reward. For each reversal, only one side was rewarded. The criterion to proceed to the next reversal was 18 passed trials out of 20 within a session. Both species showed an error reduction over consecutive reversals. Unexpectedly, the crocodiles produced significantly fewer errors than the alligators while the error curves showed a similar progression over time for either species. However, the alligators had consistently shorter latencies to manipulate the apparatus than the crocodiles. For example, in the first session of each reversal, the crocodiles took on average 43% more time to decide. Thus, the alligators were possibly more motivated to participate, which could in turn have led to a higher error number.

Crocodylians also learn to avoid chemically protected prey. Under laboratory conditions, hatchling freshwater crocodiles (*Crocodylus johnstoni*) were offered small metamorphs of the poisonous cane toad (*Rhinella marina*), which is highly invasive in Australia (Somaweera et al. 2011). The subjects were collected from an area yet uninhabited by cane toads. The test group received alternatively cane toads or crickets on feeding nights, the control group was only offered crickets. Toad-familiar crocodiles learned to avoid eating the metamorphs but still took the crickets. The toad-naïve controls were eventually offered a cane toad and they accepted them at the same rate as crickets. Hence freshwater crocodiles can rapidly learn to avoid nauseating prey that could even be lethal if consumed in large quantities or if the cane toads were much bigger. Such learning indeed appears to happen in the wild: At locations with established cane toad populations, the crocodiles were less likely to consume the invasive species than native frogs, although either prey was available at equal rates (Somaweera et al. 2011).

Chemosensory learning in crocodylians can also occur *in ovo*. When saltwater crocodile (*Crocodylus porosus*) eggs were treated with strawberry food flavoring, the hatchlings had a preference for strawberry-flavored meat pieces (Sneddon et al. 2000). Animals hatched from untreated eggs showed no such preference. This prenatally learned association was quite specific as the hatchlings from the treatment group did not discriminate between unflavored food and meat coated with orange flavoring.

## Physical Cognition

### Object Manipulation

The subduing and subsequent manipulation of prey items is probably the most common case of object manipulation in crocodylians. One challenge facing an animal is the act of picking up small objects from the ground. Due to the position of their eyes, it is often difficult to see an object or prey item if the item is not higher than their jaws. Additionally, crocodylians also lack a lot of flexibility in their neck. Thus, they twist their whole anterior body (Grigg and Kirshner 2015). This allows them to see the object or prey item and helps them grab it. When manipulating an item, crocodylians often make use of a strategy called *inertial feeding* (Grigg and Kirshner 2015). Herein, they quickly release the item and shift the grip of their jaws to a new position, relying on the item's inertia to stay put as they change the grip.

### The Potential for Tool Use

In 2013, Dinets et al. claimed to have observed a case of tool use in two crocodylian species: American alligators and mugger crocodiles (*Crocodylus palustris*) supposedly display sticks on their snouts while floating on the water surface to lure wading birds in search of nesting materials. This behavior was initially observed in captivity, at two sites where trees inside the crocodylian enclosures are used as rookeries by wild egrets and other birds. Dinets et al. (2013) reported that specimens of both species were occasionally observed balancing sticks on their snouts during

the birds' nesting season. On one occasion, an egret tried to take the stick off the snout of a mugger crocodile which led to an unsuccessful predation attempt. The authors reported anecdotal observations of American alligators catching wading birds which reached for the displayed sticks. However, none of these instances were documented and the mugger crocodile's observation is the only one described in detail. Dinets et al. (2013) further conducted a more systematic study of the behavior. They reported that American alligators also balanced sticks on their snouts in the wild and that they were more likely to display this behavior close to rookeries of nesting birds and further likelier during nesting season. The authors took these observations as evidence of tool use in crocodylians.

However, Dinets et al. (2013) did not report a single predation attempt resulting from this behavior during their systematic observations. Thus, the goal of the purported tool use was never observed. Dinets et al. (2013) also never discuss how crocodiles or alligators pick up sticks to balance them on their snouts. They only report instances where sticks were already being displayed. This raises the question of whether there was any manipulation of the supposed tool. It is plausible that the presence of rookeries, and hence birds fighting over nesting material, increases the number of sticks in the water. The sticks could have floated or dropped onto the snouts of the crocodylians by accident. However, Dinets et al. (2013) argue that this is not a likely explanation because they did not observe a higher number of sticks than normal floating in the water during these periods.

The claims of Dinets et al. received considerable attention, despite their study mainly providing a hypothesis based on anecdotes and not actual documentation of crocodylian tool use. Besides the above-mentioned issue on true tool manipulation, the stick-balancing behavior is probably not an efficient luring method. Crocodylians cannot snap for birds directly above their snout. Luring behavior usually involves releasing the tool after manipulation as was observed in wading birds. If crocodylians would let the stick float close to their head, they could launch for approaching

prey. Additionally, wading birds actively seek out areas with a high abundance of crocodylians to build their nests in the trees above them. The presence of crocodylians prevents other predators from climbing the trees and looting the nests. The birds are hence aware of the presence of crocodylians, which reduces the chances of luring to be successful.

A recent study by Rosenblatt and Johnson (2020) attempted to empirically test the hypothesis raised in Dinets et al. (2013). They investigated the stick displaying behavior at four sites with captive populations of American alligators: two with rookeries and two without. The observation periods for each site were chosen in a way to standardize the temperature and the arrival of the birds at the nesting places. Only sites with rookeries had floating sticks in the water already. Rosenblatt and Johnson added sticks to all pools to achieve equal coverage at each site and to increase the opportunity for stick balancing. They found that the alligators living at sites with no nesting birds displayed as much stick balancing as the alligators living under rookeries. In fact, at the site without rookeries and the smallest study population, alligators displayed more stick balancing than at the site with rookeries and the largest number of subjects. The latter site incidentally was also the only location where Dinets et al. reported to have observed successful predation connected to the stick displaying behavior. It was significantly colder at the smaller site without a rookery than at the other locations during the observation period; hence the alligators might have moved less and sticks had a slightly higher chance to get caught on their snout by accident. Overall, sticks were only rarely observed on alligators' snouts and usually they stayed there for less than 1 min. Instances where the "stick-balancing" behavior lasted longer than 10 min only occurred at sites with rookeries. But these observations were so rare that they are best explained with a sampling bias, as these sites had much larger alligator populations than those without rookeries.

In summary, it is plausible that few crocodylians which caught inattentive wading birds at rookery sites also happened to have

floating sticks stuck on their snouts. However, there is no empirical evidence for any crocodylian to purposefully manipulate a stick and subsequently present it on its snout with the goal to lure prey. This does not mean that crocodylians are incapable of tool use though. Empirical evaluations of anecdotal observations have a large potential to reveal more about crocodylian physical cognition in the future.

## Spatial Cognition

An important aspect of spatial cognition is the ability to return to one's familiar home range or territory, also called "homing." Several crocodylian species have been documented to home over large distances (Read et al. 2007). It is still unclear how they achieve this. Crocodylians might be able to use beacons (cues close to their goal) and landmarks (cues associated with the direction to the goal). Such cues might be sufficient in river habitats, where an animal can move up or down stream. However, crocodylians mostly travel by swimming and are hence at the lowest elevation in a landscape, which results in a suboptimal overview.

Some preliminary evidence suggests that crocodylians might be sensitive to the earth's magnetic field, which would greatly contribute to their homing abilities. In several parts of the world, it is common practice to capture nuisance crocodylians and release them in less populated areas. However, the animals will often home back to the place of capture. During relocation efforts of spectacled caimans and crocodiles in Mexico, Dominguez-Laso (2007) frequently observed such homing behavior. But he found that if magnets were taped to their cranial plates or ear flaps after capture, and removed shortly before their release, the crocodylians were unable to travel back to their place of capture. The crocodylians who had the magnets attached also moved their heads back and forth after release, as if trying to orient themselves, further indicating the presence of magnetoreception. However, to date, there has been no systematic experiment studying the presence of magnetoreception in crocodylians.

The best empirical data for long-distance navigation comes from capture–release studies on saltwater crocodiles in Northern Australia. Mature individuals can home over hundreds of kilometers. They travel along the coast, exploring several rivers, and often reach their capture site within a month. The crocodiles appear to follow external cues. The earth's magnetic field is the prime candidate, yet others are also possible, for example, stellar constellation or scents (Fukuda et al. 2019). Their homing can however be disrupted by large obstacles such as peninsulas between capture and release sites. If passing the obstacle requires extensive detouring (involving temporarily swimming in the direction toward the capture site), saltwater crocodiles appear to be unable to home. However, even substantial obstacles can be circumnavigated if the crocodile does not have to swim in the opposite direction. On one occasion, a large male saltwater crocodile was captured at the western side of the Cape York Peninsula and flown by helicopter overland (120 km) to a river on the eastern side. After spending 3 months around the release site, the animal swam along the coast up north to the cape, rounded it, and traveled south back to its capture site. It needed a month for this 411 km long journey (Read et al. 2007). The geography of Cape York (relatively straight coastlines) and its ocean currents might make it an ineffective obstacle for homing nuisance crocodiles, despite its substantial size.

Tracking data also suggests that some crocodylians might have in-depth knowledge of vast areas outside their most frequented home range. A 3.8-m long male saltwater crocodile traveled unsolicited 935 km along the coast of eastern Queensland to a different river (Grigg and Kirshner 2015). Similarly, another saltwater crocodile left its supposed home range, spent time in two different rivers, and then returned; traveling approximately 900 km in the process (Fukuda et al. 2019). Members of the same species also travel long distances to exploit temporary feeding opportunities such as fish crossing a specific river barrage during the king tide (Grigg and Kirshner 2015). Crocodylians could have learned about these feeding grounds during the decades between

leaving their hatchling pod and establishing their territory. The extent to which long-term spatial memory and other abilities play into the navigational capacities of crocodylians is a fascinating topic for future research.

## Play

In *The genesis of animal play* (Burghardt 2005), Burghardt mentions that crocodylians seem to play or are, at least, investigative. For instance, an Orinoco crocodile (*Crocodylus intermedius*) repeatedly engaged with novel objects presented to him and a young, wild American alligator swam around and snapped at trickling water from a pipe. However, all the accounts are either anecdotal or unpublished. This is also true for a more recent, extensive review by Dinets (2015). While it is very plausible that crocodylians engage in play, and many of these anecdotal accounts indicate it, the behavior needs more rigorous research.

## Spontaneous Olfactory Discrimination

In a laboratory environment, juvenile Nile crocodiles were presented with smells from petri dishes containing either meat or water (Chabrolles et al. 2017). They showed a preference for the meat stimulus if they had fasted for 2 days. In another experiment, captive, adult American alligators were presented with two paper bags containing either meat or more paper (Scott and Weldon 1990). The alligators took the meat bags more often than the controls. The alligators grabbed the control bag on several occasions but then let go without taking it; this occurred at much lower rates with the test bag. This suggests it was a challenge to go by smell alone at smaller distances and that they also used gustation to locate the food. Young American alligators also discriminate between the smells of different food items which was shown by measuring consistently different rates of gular pumping, a behavior primarily associated with sniffing in crocodylians (Weldon et al. 1992).

## Social Cognition

The different species of crocodylians vary substantially in their degree of social tolerance. All of them start in a pod with their siblings and actively seek each other's presence. For example, one study showed that hatchling American alligators preferred to group with other alligators rather than seek shelter, but they had no preference for kin over nonkin (Passek and Gillingham 1999). As adults, some species are highly territorial, while others still aggregate frequently throughout life.

All crocodylians have a rich repertoire of social signals and these are, with few exceptions, universal across the entire order. The best-studied modality is vocal communication. For instance, nest guarding female Nile crocodiles excavate their clutch when they hear their offspring call *in ovo* shortly before hatching. These "prehatching calls" are also perceived by siblings and animate them to hatch themselves (Vergne and Mathevon 2008). When swimming in the pod under parental protection, small crocodylians frequently produce "contact calls" during foraging and "distress calls" if threatened by a predator. The two calls are graded and mainly differ due to a steeper downward frequency modulation in distress calls. Hatchlings discriminate between these two calls despite their differences being subtle. In playback experiments with wild young black caimans (*Melanosuchus niger*), subjects moved into the general direction of a loudspeaker playing contact calls but froze when hearing distress calls (Vergne et al. 2011). The guarding mothers did not respond to the contact calls but approached the distress calls, which indicates that this vocalization recruits parental protection. It also carries cues to the callers' body size, which are perceived by adults. Nest guarding female Nile crocodiles preferably approach calls of smaller juveniles (Chabert et al. 2015). Contact calls in contrast appear to be strongly linked to group cohesion during foraging, which is also supported by the finding that unsated Nile crocodiles were more likely to approach an olfactory food stimulus if they simultaneously heard contact calls (Chabrolles et al. 2017).

## Cognitive Capacities Inferred by Observation

### Hunting and Feeding

Crocodylians' main hunting tactic for terrestrial animals is to lie submerged in wait for prey to drink at the water's edge and propel themselves out of the water at the opportune moment. Crocodylians must inhibit this response until the prey is in range and then respond with full force. While this is true for most predators, the instant switch from complete stasis to strike is probably most extreme in crocodylians. Detailed studies on their inhibition capacities have not been published to date.

A fishing strategy exhibited by yacare caimans (*Caiman yacare*) and saltwater crocodiles involves cruising at the water's surface and stretching out their forelimbs at right angles with raised, outward-facing hands. They then snap at fish that swim close to their heads or hands (Grigg and Kirshner 2015). A modern development within cognitive science is to not view cognition as being situated solely in the brain but to see it as embodied or even extended out into the world. This fishing strategy exemplifies the type of cognitive behaviors that this view would highlight. The crocodylian stretches its limbs out into the water to extend the area it is situated in and, thus, increases the likelihood of capturing prey.

### Nesting

Crocodylians have two modes of nesting: hole nesting and mound nesting. Approximately a third of crocodylians dig holes for their nests (Grigg and Kirshner 2015). Mound nesters include all Alligatoridae, around half of Crocodylidae, and false gharials (*Tomistoma schlegelii*) (Grigg and Kirshner 2015). The nest building can be quite involved and poses many cognitive challenges: for example, the choice of a suitable nest site. Crocodylians have temperature-dependent sex determination with only a narrow temperature range producing offspring of both sexes. Thus, the nesting site needs to have appropriate levels of warmth and moisture. Female crocodylians have been documented to abandon previous nesting grounds for sites with lower,

more stable temperatures and moisture (Grigg and Kirshner 2015). A mound is built over a period of several days or even weeks and can be comprised of a variety of materials like vegetation, soil, sand, shells, etc. The availability of materials such as these also play a role in site selection; however, crocodylians have also been shown to be flexible in this regard and make do with what is available (Grigg and Kirshner 2015). Some species are even flexible when it comes to what type of nests they build (Grigg and Kirshner 2015). Observations like these could indicate that nest building is a deliberate behavior, informed and affected by the environment.

## Conclusions

Crocodylians have striking learning and navigational abilities that are still not well understood. They also have a social repertoire which is in many ways more reminiscent of birds and mammals than other nonavian reptiles. They are a natural extension of the cognitive research conducted on birds. Due to their phylogenetic position, they may teach us much about cognitive capacities in extinct dinosaurs and the evolution of cognition in general. Cognitive research on crocodylians, particularly detailed experimental investigation, is still sparse. This is partly owed to their adult size and the accompanying handling risks. However, the cognitive capacities of most nonavian reptiles have not been studied to a comparable extent as those in other amniote taxa. The reasons for that are manifold and range from mere practical challenges to the persistence of a "*scala naturae*" inspired view of the natural world. In this chapter, we attempted to summarize the existing knowledge and highlight the potential for future research in comparative crocodylia cognition.

### Synonyms

Crocodylian Communication; Crocodilia Communication; Crocodilian Communication

### Introduction

The members of the evolutionarily ancient order Crocodylia, commonly referred to as “crocodilians” possess a wide array of communication capacities in the acoustic, visual, tactile, and olfactory domain. The behavior of crocodilians has been studied in the wild and captivity for centuries, and many visual and acoustic signals have been described in detail. Yet, the actual communicative function of these behaviors is still a topic of active research. This has several reasons. For one, crocodilians cannot easily be individually identified and followed in the wild due to their semi-aquatic lifestyle. Secondly, social interactions are usually composed of multiple signaling elements, which occur in more than one context, for example, in courtship and in territorial displays. Finally, most signals are very subtle and some of them even unperceivable to humans, such as subaudible vibrations.

The extant Crocodylia species (at least 24, probably 27) belong to three taxonomic superfamilies: the “true” crocodiles (Crocodylidae), the alligators and caimans (Alligatoridae), and the gharials (Gavialidae). They differ vastly in adult body size and skull morphology, as well as in degree of territoriality and social tolerance. Nonetheless, crocodilians seem to share highly conserved, even partially interchangeable communication systems, which are most apparent in juveniles. All crocodilian species vocalize frequently in the first months of their lives, but

reduce their vocal activity throughout ontogeny. However, at adulthood the species differ greatly in the amount of vocal signals produced. Members of the Alligatoridae, particularly the American and Chinese alligator (*Alligator mississippiensis/sinensis*), are much more vocal than most crocodile species. The genus *Crocodylus* is especially silent and the vocalizations of some of its species have hardly ever been recorded (Grigg and Kirshner 2015). Yet, despite the dissimilar usage of acoustic signals, it is most probable that crocodilians possess one universal call repertoire (Britton 2001). All species use a multitude of visual signals for communication. Chemical signals and infrasonic vibration are still very poorly studied, but it is suspected that they play an important role in all crocodilians.

### Body Postures

Even with only parts of their body visible above the water surface, crocodilians can signal their status to conspecifics with the angle of their heads and the height of their backs. Dominant individuals raise the back of their heads disproportionately out of the water and the post-occipitals (plates caudal to the skull) are visible. In addition, a large portion of the back is above the surface (“*inflated posture*” (Garrick and Lang 1977)). Subordinate animals keep their back below the surface and hold their head low. If a dominant animal approaches a subordinate, the latter can avoid a confrontation by swimming away in this “low-profile” posture or by submerging. During a high-walk (not touching the ground with the ventral side) on land, a dominant crocodilian curves its back slightly upwards while keeping the tip of the snout low (see Fig. 1), and subordinates move out of its line of direction. Approaching a conspecific with a wide-open mouth is a clear sign of threat and aggression (Grigg and Kirshner 2015). As a sign of submission, the approached individual can raise its snout tip high up with the jaws tightly closed and displaying its vulnerable gular pouch (Garrick and Lang 1977). This signal usually has an appeasing effect and the dominant individual

**Crocodylia Communication, Fig. 1** Dominance interaction in subadult American alligators: The individual on the right displays dominance with a raised back, open mouth, and low-held nose tip. (Photo by Adrian Hiss)

gradually closes its mouth while the subordinate follows by lowering its head back to the ground.

### Tactile Communication

Crocodylians have pressure sensitive receptors in their skin, so-called integumentary sensory organs (ISO). In crocodiles, ISOs are found all over the body, while in the Alligatoridae they are limited to the jaw region (Leitch and Catania 2012). Besides their importance for hunting under water, these organs are also relevant in affiliative contexts. Particularly during courtship, mates rub their jaws slowly against each other (Vliet 2001), stimulating their own and their partner's ISOs.

### Nonvocal Acoustic Signals

A typical crocodilian threat signal is the “jaw clap,” a rapid closing of the mouth with the head lifted off the ground, which produces a loud “pop” sound (Garrick and Lang 1977). Directed at conspecifics or heterospecifics, it occurs in a variety of contexts including female nest defense and territorial intrusion. As part of a territorial display, jaw claps are often combined with “headslaps,” a behavior performed exclusively in the water wherein the head is explosively smashed onto the surface creating a splashing noise (Garrick and Lang 1977). For instance, a male American alligator will raise its head and tail out of the water, resulting in the “head oblique, tail arched”

(HOTA) position (Garrick and Lang 1977) and stay motionless for at least a few seconds. Then he will quickly open his mouth and produce a jaw clap (some individuals produce several) simultaneously hitting the water with the lower surface of the head (Vliet 1989). Following the headslap, the alligator will wag its tail ferociously from side to side thereby stirring up the water. Fainter tail wags may precede the headslap, and in some cases this display will include subaudible vibrations (SAV) and low-pitched growling. This entire behavioral series appears to mainly serve as an advertisement display announcing an individual's presence (Vliet 1989). It is performed most frequently during breeding season but may occur throughout the year. In contrast to bellowing (see below), however, it seems to be mostly directed at potential rivals and is more antagonistic. Similar forms of the headslap display have been observed across crocodilians yet with some elements differing or missing; for example infrasonic vibrations appear entirely absent in gharials (Grigg and Kirshner 2015). Before adopting the HOTA position, crocodilians frequently perform “narial geysering,” the rapid and forceful expulsion of air through the nostrils (Garrick and Lang 1977). If the snout is only slightly submerged, this results in small fountains of water droplets being thrown up (“geyser”-ing), thereby producing a loud snorting sound. Crocodilians also geyser when fully submerged, which creates a stream of air bubbles and the accompanying noises. Although narial geysering is commonly observed in territorial displays, it is also associated with courtship.

Crocodylians may swim under the head of a potential mate and blow bubbles, which then float against the gular pouch and from there past the jaw bones, caressing the ISOs (Vliet 2001).

## Vocal Communication

### “Prehatching” and “Posthatching” Calls

Crocodylians already start to vocalize while still in the egg. “Prehatching calls” can usually be heard outside the nest a few hours before hatching, but may already occur up to 5 days earlier (Somaweera and Shine 2012). These calls are acoustically distinct from calls given after hatching (“posthatching calls”) by being shorter, having less sound energy, and a lower peak frequency (Britton 2001). All these differences could be explained by the filter properties of the egg shell (Vergne et al. 2009). Calling in the egg has two probable functions. Firstly, crocodilian prehatching calls are directed at siblings and synchronize hatching. Nile crocodiles (*Crocodylus niloticus*) inside the egg respond to the prehatching calls of their siblings by calling back (Vergne and Mathevon 2008). Moreover, these calls actually stimulate the animals to hatch. Secondly, the prehatching calls are a signal to the mother to excavate the nest and aid the hatchlings to reach the water. Crocodylians build two main nest types: mounds and holes (Grigg and Kirshner 2015). Although hatchlings have been reported to escape from either without assistance, hardened substrate around the eggs can trap them, particularly in hole nests with sand (Somaweera and Shine 2012). Nile crocodile females respond to prehatching calls emerging from a substrate close to their nest by digging for the sound source (Vergne and Mathevon 2008). Immediately after hatching, young crocodylians keep calling to attract their mother. Once the female excavates the clutch, she carries hatchlings and also yet-unhatched eggs in her gular pouch to the water. There she gently cracks the eggs open and frees the hatchlings (Grigg and Kirshner 2015). However, she does not pick up any egg indiscriminately. In freshwater crocodiles (*Crocodylus johnstoni*), mothers ignore infertile

eggs (Somaweera and Shine 2012). Although it has never been investigated, it is possible that females focus their care on eggs from which they hear calls. The vocalizations of hatchlings change already in the first 4 days after leaving the egg (e.g., the fundamental frequency decreases (Vergne et al. 2007)). As will be explored in more detail below, higher frequency juvenile calls are more effective in recruiting parental attention, which could explain this finding. A hatchling might call at particularly high frequencies directly after hatching to elicit the picking up behavior from its parent, because of the high predation risk on the way from the nest to the water. There is no consensus whether these “posthatching calls” are a distinct call type. Structurally they are similar to “distress calls”; however, the context and the behavior of the hatchlings do not compare with a predator encounter.

### “Contact” Calls

Right after hatching and throughout their years as juveniles, all crocodylians frequently and spontaneously produce quiet chirps, which are commonly termed “contact calls” in the modern literature (Vergne et al. 2012). Previously they were also referred to as “grunts” or “barks” (Campbell 1973; Herzog and Burghardt 1977). Contact calls are highly stereotyped vocalizations characterized by clear harmonics and a strong frequency modulation (see Fig. 2a). A call starts with a temporally short up-sweep and ends with a longer (~75% total duration) down-sweep (Vergne et al. 2012). Contact calls are produced in a variety of nonpredator contexts, including foraging and moving in a group of juveniles (Herzog and Burghardt 1977). It was suggested that these calls serve group-cohesion because siblings forage together after hatching and prefer conspecific contact over shelter (Campbell 1973; Passek and Gillingham 1999). Young black caiman (*Melanosuchus niger*) juveniles, still guarded by their mother, responded to conspecific contact calls by gradually moving towards the sound source (Vergne et al. 2011). Contact calls are a great example for the initially mentioned potential universality of crocodilian communication. Nile crocodile juveniles do not discriminate between

**Crocodylia****Communication,**

**Fig. 2** Contact (a) and distress call (b) of American alligator juveniles of the same age, both 30 cm long (window length [s]: 0.025; dynamic range [rel dB]: 30.0)

the contact calls of conspecifics, black caimans, and spectacled caimans (*Caiman crocodilus*) (Vergne et al. 2012). Moreover, Nile crocodile and spectacled caiman juveniles show the same responses to natural contact calls and modified synthetic copies of contact calls, which only contain the first harmonic (Vergne et al. 2012). This strongly suggests that the above-mentioned frequency modulation is the key parameter defining this call type, neither amplitude modulation nor other harmonics appear to be necessary. Members of the Crocodylidae (*C. niloticus*) and Alligatoridae (*C. crocodilus*) are the most distantly related recent crocodilians. Hence, contact calls and their function are probably ancestral for the entire taxonomic order.

**“Distress” Calls**

When young crocodilians feel threatened by a predator or a hostile conspecific, they produce several “distress calls” in quick succession. These vocalizations are structurally very similar to contact calls, yet much louder, with a higher initial frequency, and a more pronounced

frequency modulation (see Fig. 2b) (Britton 2001; Vergne et al. 2011). Distress and contact calls grade into one another but are contextually distinct (Vergne et al. 2011). The main function of distress calls is to elicit maternal protection. Adult females approach the source of distress calls to fend off predators. The calls also cause responses from nearby juveniles: young black caimans react to distress calls by freezing in place and starting a chorus of distress calls themselves (Vergne et al. 2011). Mothers are much more likely to approach distress calls than contact calls. This suggests that the contagiousness of distress calling is a mechanism to increase the effectiveness of the recruitment of the mother. The responsiveness of female crocodilians to distress calls also depends on the age and size of their producers. The fundamental frequency of distress calls decreases with increasing body size of juveniles in at least five, and probably all, crocodilian species (Chabert et al. 2015). Female Nile crocodiles, either guarding their nest or hatchlings, respond with more approaches when hearing distress calls from small juveniles (total length 28–36 cm) than

from large ones (63.5–98 cm) (Chabert et al. 2015). Larger juveniles are usually no longer under maternal protection and are potential predators of smaller individuals themselves, which explains why adult females would preferably come to the aid of smaller juveniles. With increasing size, crocodilians produce fewer distress calls, probably because there are also progressively fewer predators large enough to threaten them (Britton 2001). However, subadults and even adult crocodilians utter distress calls on rare occasions, e.g., when losing a physical fight with a conspecific and trying to escape their opponent's jaws.

### Hissing

Most crocodilian species have been reported to hiss when threatened (Garrick et al. 1978; Vergne et al. 2009). In contrast to distress calls, hissing signals a readiness to fight and bite. Before and during a hiss, an animal would usually inflate its lungs, stand with its ventral side lifted off the ground, and the mouth slightly open. A hiss is a loud and long vocalization (>1 s) produced by a rapid expulsion of air through the glottis (Britton 2001). It is a chaotic, broadband call with no clear harmonic structure (Fig. 3).

### Bellowing and Roaring

The most conspicuous vocalizations in any non-avian reptile are the long-distance calls of crocodilians, commonly termed “bellows” in alligators and “roars” in crocodiles (Grigg and Kirshner 2015). As initially mentioned, crocodilians vary in vocal activity and bellowing/roaring are the best examples. All crocodilians seem to show a variation of this behavior, but members of the Alligatoridae bellow most frequently. It is usually performed in water, preferable in shallows, but it has been observed on land as well. The bellowing of a male American alligator is used as an example here (Fig. 4). The animal adopts the HOTA position before bellowing; if on land, the tail remains on the ground, but the head is maximally raised. The alligator lifts its body out of the water, the head is at the highest point, and the back and the neck are above the surface. During this motion, he audibly inhales maximally; a constriction of the gular pouch suggests that he additionally pushes air down into the lungs. Then the alligator lowers itself into the water until the entire back is submerged. In this position, he produces subaudible (infrasonic) vibrations (SAV), which can be felt by a human standing 20 meters away. The vibrations are so strong, they make the water seemingly

**Crocodylia

**Crocodylia Communication, Fig. 5** Bellow of an adult male American alligator; notice the artifact of subaudible vibrations in the first quarter of the recording (window length [s]: 0.15; dynamic range [rel dB]: 40.0)

boil over the alligator’s back: droplets of water are sprayed upwards above the torso. This phenomenon is commonly referred to as the “water dance” (Vliet 1989). Directly following the SAV, the alligator produces the loud bellow, a rumbling, low-pitched, pulsed vocalization (Fig. 5). Usually the animal will inhale again after the first call, sink back into the water, and produce a second one. A bellowing bout commonly contains three to four calls, which grow shorter and less powerful within the series. The bellowing behavior is

sexually distinct as females do not produce SAV and hence display no water dance. However, both sexes are equally acoustically active (Garrrick et al. 1978). There are not enough empirical data on bellowing and roaring to conclude that this sexual dimorphism holds up across crocodilians. It is also uncertain whether all species even produce SAV, although it appears to be widespread (Grigg and Kirshner 2015). As crocodiles have ISOs all over their body, it is conceivable that SAV are even more important in Crocodylidae than

Alligatoridae. The actual communicative function of bellows is still not conclusively clarified. The behavior is shown year-round with the highest occurrence during the mating season. It precedes rival confrontations as well as mating. Therefore, it is commonly thought to be a territorial and a courtship display. Yet, bellowing is a contagious behavior causing animals to aggregate and to form bellowing choruses, e.g., in Chinese alligators (Wang et al. 2009). Aggression is rare in these situations, making it unlikely that it mainly serves territoriality. Bellowing and roaring are hence best described as advertisement calls (Dinets 2011). They potentially have similar function as self-aggrandizing displays in birds, which are the closest living relatives of crocodilians. It has been suggested that bellows advertise a caller's physical attributes (Garrick et al. 1978), e.g., body size. Acoustic cues to size in vocalizations of mammals are usually encoded in the distribution of the resonances ("formants") in the sound spectrum (Charlton and Reby 2016). The discovery of formants in the bellows of a female Chinese alligator was the first evidence of its kind in any nonavian reptile (Reber et al. 2015). In American alligators, the distribution of formants in bellows is strongly negatively correlated with a caller's body size (Reber et al. 2017). For instance, the distance between the first and the second formant in a smaller male (total length: 298 cm) is ~300 Hz, while in a larger male (390 cm) it is ~140 Hz. Lower formants hence indicate larger individuals. The dominant frequency is not an indicator of body size. In some other animals, e.g., red deer, callers actively extend the length of their vocal tract during vocalizations to produce lower formants (Charlton and Reby 2016). There is indirect evidence that American alligators do the same. The vocal tract during bellowing consists of the nasal and the pharyngeal cavity, and in order to extend it to its maximum length, an alligator could pull the larynx down towards the sternum. During the audible bellow, there is clear muscular tension in the pharyngeal region and a pouch is forming around the location of the larynx. This pouch probably contains the massive tongue, which is directly connected to the hyoid cradling the larynx (Riede et al. 2015). If alligators indeed pull the

larynx down, this behavior is probably easier to perform on land than in water (e.g., due to buoyancy). The bellows of American alligators have lower first formants if produced on land than in water, and the formant distribution on land indicates a more uniform tube-like ("stretched") shape of the vocal tract (Reber et al. 2017). Taken together, these findings confirm the hypothesis that bellows and roars are advertisement calls.

### Other Vocalizations

Crocodylians produce a range of other vocalizations which have received little attention to date. Adults of several species produce very low-pitched and silent grunts in close proximity, which probably serve as affiliative signals. Females guarding offspring frequently utter low rumbles, which were sometimes referred to as "burp-trill" (Hunt and Watanabe 1982) and seem to attract the hatchlings. When seized, young crocodilians may produce "annoyance calls" (Britton 2001), broadband high-frequency vocalizations, which are acoustically distinct from 'normal' distress calls; it is unclear whether they might be distress calls with altered properties due to the effect of seizing. Male Indian gharials (*Gavialis gangeticus*) have a bulbous outgrowth, a "ghara" (Hindi: "pot"), above the nostrils. It amplifies loud snorting hisses (Whitaker 2007), that might be an equivalent of bellowing/roaring in other crocodilians. Whether the "ghara" contains vibrating tissue or acts as a cavity resonator is unknown.

### Subaudible Vibrations (SAV)

The water-dance before bellowing in male alligators and similar signals in other crocodilians are clear indicators of strong vibrations below the human hearing range, hence called "subaudible vibrations" or "infrasound." Yet, these SAVs can be felt by humans, similar to the low bass from a large loudspeaker. There is substantial sound energy in the range of 16–25 Hz in male American alligator bellowing sequences (Todd 2007). Because SAVs are produced in the bellowing and roaring context, they almost certainly serve a communicative function. However, too many

variables are as of yet unknown and definite conclusions premature. It is neither clear how crocodilians produce infrasound nor whether they can actually hear it. Large mammals can produce infrasound with passive motions of their massive vocal folds alone, yet the vocal folds of crocodilians are minute in comparison and most probably cannot vibrate at such low frequencies. Crocodilians might produce infrasound with muscles in other body parts, e.g., in the flanks. The crocodilian ear, similarly to all reptiles including birds, is less sensitive to high frequencies compared with mammals. The hearing of young American alligators is very similar to birds (Higgs et al. 2002) and hence not very likely to perceive airborne infrasound, although adult individuals have never been tested. It is also possible that crocodilians do not actually hear SAVs but might perceive them via their ISOs alone. Given that only male American alligators produce a water dance before the audible bellow, this signal could consist of two distinct components: the presence or absence of the water dance advertises the caller's sex and the formants in the audible sound the caller's size (Reber et al. 2017).

## Olfactory Communication

The most visually apparent difference between an avian and a crocodilian brain is the large olfactory bulb in the latter (Vergne et al. 2009). Crocodilians have an acute sense of smell and it is probable that they also use it for social communication. There are three main types of skin glands in crocodilians: mandibular glands, paracloacal glands, and dorsal integumentary glands. They secrete a large variety of chemicals (Grigg and Kirshner 2015; Weldon et al. 1990), including some which are found nowhere else in nature, such as the aromatic ketone dieneackeron in the paracloacal glands of West African dwarf crocodiles (*Osteolaemus tetraspis*) (Whyte et al. 1999). As with other forms of crocodilian communication, olfactory signals are well described, but experimental data clarifying their function are still lacking. The mandibular glands are used during courtship, when males and females rub their

heads over each other (*C. niloticus* (Kofron 1991), *A. mississippiensis* (Vliet 2001)), suggesting that they serve a pheromonal role. The secretions from the paracloacal glands smell musky and float on the water surface. There are indications that they are used in territorial defense as they can be detected following the headslap behavior in American alligators (Vliet 1989). The dorsal integumentary glands are least well understood. They are found in several *Crocodylus* and both alligator species and seem to be most active shortly before and after hatching. After a few years posthatching, the glands seem to stop secreting fluids (Grigg and Kirshner 2015). These secretions are hence thought to play a role in early mother-offspring and/or sibling interactions (Grigg and Kirshner 2015).

## Conclusion

Crocodilians show a wide range of communication behaviors. Although many of them have been described in detail, their functions are in most cases still unclear. Further experimental evidence is required for a better understanding of Crocodylia communication. For example, it is now known that bellows are honest signals of body size; however, it has not been shown that the animals are actually sensitive to these cues. Acoustic communication in crocodilians is a particularly important field of study for comparative research: the crocodilian sound source is the larynx just like in mammals, yet they have a very avian-like brain structure. Therefore, crocodilians are an interesting intermediate model to study communication and cognition across amniotes.

## Cross-Fostering Studies

Patrick Drumm

Lancaster, Lancaster, OH, USA

### Introduction

A pulp magazine, *The All-Story*, published Edgar Rice Burroughs's *Tarzan of the Apes* in 1912. Its

fictional protagonist stands as a familiar icon of what we now call cross-fostering. As the story's plot unfolds, an ape adopts and nurtures the Earl of Greystoke's orphaned infant son, who matures to lead his troop of nonhuman rescuers. Burroughs later asserted, "I was mainly interested in playing with the idea of a contest between heredity and environment" (Taliaferro 1999). To better understand those two influences on phenotypic development, twentieth-century science embraced cross-fostering both conceptually and procedurally.

Conceptually, cross-fostering occurs when offspring are reared not by their biological mother/parents but by foster parents of the same or a different species. As a procedure, offspring are placed under the care of foster parents whose genetic relatedness to them researchers deliberately manipulate. Cross-fostering allows researchers to detect similarities and differences between the biological parents and the foster parents observed in the offspring. Further, it operationally establishes a means to assess hereditary and environmental consequences, as well as their interaction. An extensive literature exists on this topic.

The term cross-fostering underwent a dramatic uptick in the research literature during the 1960s. Few studies before that decade used the term even when investigating cross-fostering effects. Its unheralded coinage, though apt, compels those conducting literature searches to choose their keywords with diligence.

### Cross-Fostering and Animal Husbandry

During our own species' prehistory, the practice of domesticating other species likely included not only intentional breeding, but perhaps cross-fostering as well. In research literature, the term appeared with increasing frequency in mid-twentieth-century reports, especially in agricultural science. Under controlled conditions, some domesticated species rear and even nurse the offspring of alien species with behavioral outcomes supporting claims about the importance of early experience (Fox 1969).

## Ethology

It was also in the mid-twentieth century that ethology, the comparative study of behavior, emerged as a subdiscipline of zoology. It encompasses a broad diversity of methods, but its roots lie in the practices of field naturalists, observing animals where they found them. As they refined their methods, they began to examine, and eventually manipulate, parent-offspring relationships.

Cross-fostering sometimes does occur in nature. Both ancient Vedic texts and Aristotle noted that cuckoos deposit their eggs in other birds' nests to be incubated and reared by non-cuckoos. Payne (1977) described a number of such avian brood parasites. The adaptive payoff of exploiting hosts' parental investment seems obvious, but other reports document apparently accidental cross-fostering among birds. For example, two species of Australian cockatoos may nest in the same tree hollow and deposit eggs in the same clutch (Chapman and Rowley 1986). When the larger species eventually displaces the smaller in disputes over the nest, the winners then rear the hatchlings of both species. The cross-fosterlings' calls, diet, and social behavior closely resemble their foster parents and may even account for reported cases of hybrids. This outcome is interesting because, as Tinbergen (1989/1951) noted, some species kill offspring they do not recognize as their own.

Ethologists asserted that imprinting produces effects like those cases, described above, where parents wind up rearing the young of an alien species. Eckhard Hess (1959) summarized early research on imprinting, which is said to occur when innately organized responses to specific releasing stimuli promote lasting behavior patterns. Critical periods can be important insofar as the timing of stimulus onset constrains response activation. To illustrate with a common example, newly hatched ducklings soon follow the first moving object they encounter. That moving object, the releasing stimulus, is normally their mother. But it could in fact be any moving entity and loses the power to trigger proximity-seeking behavior when stimulus exposure is delayed by just a few days. The lasting effects of

imprinting include adult affiliative behavior. Douglas Spalding (1954/1873) rightly deserves the credit for first documenting the phenomenon now known as imprinting and for cross-fostering some of his subjects, probably inadvertently.

Deliberate cross-fostering between bird species by Whitman (1919) and his protégé, Craig (1908), demonstrated mating preferences manifested in adulthood. Upon reaching sexual maturity, birds tended to court members of their foster parents' species. The contributions of these two men, along with the earlier work of Spalding, laid a foundation for the emergence of modern ethology.

## Epigenetics

Since Conrad Waddington (1942) coined the term epigenetics, both biology and psychology have endorsed its explanatory value. Broadly construed, it seeks to identify bi-directional interactions between hereditary and environmental factors that influence phenotypic outcomes. Numerous studies using cross-fostering procedures have contributed to the growing field of epigenetics.

That body of cross-fostering research considers potential genetic and environmental influences on many variables, from behavior, cognition, and emotionality to socialization, stress response, and disease susceptibility (McCarty 2017). Most of the effort focused on rodents, mammals whose life cycles facilitate research of this type. A few other researchers studied non-human primates. Those studies reported both between-species and within-species crosses with subjects living in captive colonies. From an epigenetic perspective, their reported behavioral outcomes show cross-fostering's merits in efforts to identify possible interactions of heredity and rearing environment.

One between-species cross-fostering attempt placed rhesus and Japanese macaque infants with foster mothers of the opposite species. They lived in small social groups occupying separate outdoor enclosures. The attempt's success rate supported the procedure's potential for altering

environmental experience without risking adequate maternal care or infant well-being (Owren and Dieter 1989). However, subsequent analysis of long-term effects on the cross-fosterlings' vocal development produced equivocal results when their food calls were judged to fall within species-typical normal ranges (Owren et al. 1992).

A second attempt compared the development of hand preference, as measured by a simple bimanual task, among chimpanzees raised from infancy by their biological mothers with a comparison group of chimpanzees nursery-raised by humans (Hopkins 1999). Both groups were comparably large and composed of individuals identified within the captive colony from existing records (i.e., mother vs. nursery-reared). By the time of testing, all were living in colony enclosures. Hopkins (1999) concluded that chimpanzees display population-level right-handedness unaccounted for by genetic factors. A later replication with a different sample produced similar results (Hopkins et al. 2003), and a subsequent meta-analysis reached the same conclusion for both chimpanzees and bonobos (Hopkins 2006). Although the absence of cross-fostering effects in Hopkins (1999) and Hopkins et al. (2003) did support the conclusions in this series of studies, it may be wise to bear in mind methodological difficulties associated with cross-fostering (Gardner and Gardner 1998, pp. 7–8; Winney et al. 2015).

Stephen Suomi (1997) reported results based on within-species crosses of rhesus macaque infants with either aberrant or normal temperaments. Adverse consequences tend to befall youngsters who exhibit high reactivity or impulsivity. High-reactive monkeys respond to environmental disruptions with agitation and physiological arousal of greater magnitude than their normal peers. Impulsive individuals risk social encounters with conspecifics that escalate into self-injurious aggressive incidents, or they may suffer injuries if they misjudge treetop leaps. Although a minority of young monkeys display such temperamental deviations, long-term consequences can seriously disadvantage them. Worse, both traits are highly heritable. By selectively breeding infants likely to display those traits and then cross-fostering them with

unrelated, experienced mothers, the potential effects of two maternal styles could be assessed. Foster mothers were pre-selected based on their maternal behavior, and the cross-fosterlings were reared with either highly nurturant mothers or with mothers whose maternal behavior fell within the normal range. From within their first 4 days of life until 6 months of age, the infants were reared by foster mothers before moving to larger groups in the captive colony. The at-risk cross-fosterlings reared by nurturant mothers developed more secure attachments than normal infants raised by either nurturant or control mothers. Those at-risk cross-fosterlings reared by control mothers however displayed the expected behavioral deficits. Remarkably, the monkeys foster-reared by nurturant mothers became socially adept and could even achieve high social status in their groups. Those reared by control mothers achieved no such success. Further, at-risk females acquired the nurturant maternal style of their foster mothers, thereby passing on the benefits of that style to the subsequent generation. Thus, cross-fostering of this sort influences heritability of a nurturant maternal style.

Much contemporary epigenetic research focuses on our own species. Adoption studies arguably illustrate within-species cross-fostering applied to gauge the heritability of a variety of human attributes and behaviors. For human hand preference, such family studies once supported a view that heredity was the more powerful determining factor (Carter-Saltzman 1980). Recent molecular genetic research has tempered that view. Asymmetries of gene expression in the central nervous system apparently arise via interaction with environmental changes from conception through childhood to epigenetically mediate phenotypic variance in handedness (Schmitz et al. 2017).

## Apes Cross-Fostered by Humans

Burroughs's Tarzan novel capitalized on centuries-long interest on the part of scholars and laypeople alike in purported cases of "wild children." By the eighteenth century, such alleged cases of feral children, perhaps reared by

nonhumans, began to provoke serious scrutiny and debate (Benzaquén 2006; Newton 2002). At the close of that century, Victor, the Wild Boy of Aveyron, became the subject of an intensive investigation which left many questions unanswered (Lane 1976; Shattuck 1980). Believing psychological science could answer some of those questions, Winthrop Kellogg chose an empirical approach. After considering the theoretical and ethical ramifications of existing historical accounts, and a more recent report on the “wolf children of Midnapore,” he designed an experiment that cross-fostered a chimpanzee to human parents (Kellogg and Kellogg 1933). Kellogg and his spouse, Luella, assumed the roles of parents and collaborators.

A zeitgeist clearly had inspired the Kelloggs. Not long before Burroughs created his famous fictional character, Lightner Witmer (1909, p. 205) predicted that “within a few years chimpanzees will be taken early in life and subjected for purposes of scientific investigation to a course or procedure more closely resembling that which is accorded the human child.” Echoing Witmer’s emphasis on scientific procedure, Kellogg and Kellogg (1933, p. 12) insisted “. . . that the *psychological* as well as the *physical* features of the environment be entirely of a human character.” Beginning in mid-1931, they simultaneously raised, observed, and tested a female infant chimpanzee alongside their own son. The 9-month project collected a staggering amount of data, which ironically may have interfered with its cross-fostering goals. Most children do not experience such a rigorous testing regimen as routine aspects of their physical or psychological environments. Nevertheless, the Kelloggs’ cross-species comparisons present a remarkable set of similar developmental patterns. In a number of ways, the chimpanzee outperformed the child, for example, learning certain tasks more quickly. That might be attributed to her more rapid rate of maturation, but the human behaviors she acquired clearly depended on her experience in a human environment. With respect to language, her comprehension at first exceeded the boy’s. However, she never matched his ability to imitate vocalizations or ultimately to speak.

Research in Russia foreshadowed the Kelloggs’ comparison of child and chimpanzee. Although it did not follow the rigorous specifications for cross-fostering they set, the same aforementioned zeitgeist perhaps inspired it. In 1913, a young student at Moscow’s Women’s Advanced Courses Institute began observing the behavioral, cognitive, and emotional development of an infant chimpanzee (Ladygina-Kohts 2002/1935). Until his death in 1916, that chimpanzee lived with Ladygina-Kohts and her spouse, accompanying them on walks through the town, riding in carriages or on trains, and visiting wooded areas. He was however caged in a separate room at night or when his caregivers fulfilled other obligations. Ladygina-Kohts’s detailed observations preceded similar observations of her own son, born in 1925. Sequential observational periods of a chimpanzee and a Russian boy yielded important developmental comparisons. Unfortunately, a full English translation of her work did not appear until 2002, at last allowing Western scholars to compare it with that of the Kelloggs.

Neither the Kelloggs nor Ladygina-Kohts reported successful language production from their subjects. Addressing that lingering question became one of the goals of Keith and Cathy Hayes when they adopted a 3-day-old chimpanzee in 1947 (Hayes 1951). For 7 years, they raised her in their Florida home near the Yerkes Laboratories of Primate Biology where she was born. Their efforts paid off. Their subject’s vocal accomplishments and deficiencies established useful parameters for future research. By the time of her illness-induced death, young Viki could say seven “words,” four of which were crudely pronounced English words, primarily to make requests (Hayes and Nissen 1971). She also effectively communicated with gestures and pictures mounted on cards. Her behavior differed from both wild and captive chimpanzees in many noteworthy respects, and her spoken vocabulary exceeded that of any chimpanzee previously studied. Nevertheless, an inescapable conclusion emerged that speech was not the appropriate communication medium to explore with chimpanzees. The claim that human speech depends on specific vocal tract structures (Lieberman 1968), if valid,

may deprive nonhuman primates of the vocal capacity to produce it.

Allen and Trixie Gardner (1994) applied the Hayes's approach in two sequential projects cross-fostering a total of five chimpanzees. The first project began in 1966 and lasted 51 months with a single subject. The second began in 1972 and continued until 1981. All the chimpanzees lived approximately as human children do and were exposed to American Sign Language (ASL), the language of deaf culture in North America. Detailed daily records and a number of controlled tests documented the acquisition of ASL signs and their use by the five. The Gardners reported consistent year-by-year vocabulary growth, although by age 3, the chimpanzees fell behind human 3-year-olds, with incremental gaps each succeeding year.

The Gardners' success spawned several attempts at replication, which met the high cross-fostering standards set by the Kelloggs and the Hayeses to varying degrees. Some of those projects studied other ape species (Miles 1990; Patterson 1978), while another project again studied a common chimpanzee, relying heavily on an operant approach (Terrace et al. 1980). The latter generated considerable controversy with evidence the young chimpanzee produced ungrammatical strings of signs, many of which seemed prompted by human interlocutors. The authors also questioned the validity of other projects' published findings, arguably overstepping the bounds of scientific propriety.

It is unlikely other cross-fostering studies with apes will be conducted, and rightly so. Many researchers now acknowledge that the same ethical argument offered by the Kelloggs forbidding cross-fostering human infants to parents of other species applies in reverse. Should humans remove intelligent beings from their natural mothers for the purpose of scientific inquiry? I believe I am not alone in stating the answer is no.

## Definition

Cross-modal transfer is the transfer of information from one sensory modality to another sensory modality.

Cross-modal transfer is a difficult concept to measure due to its somewhat abstract nature. While its definition is rather simple, that is, the transfer of information from one sensory modality to another, examining it can prove to be rather complicated. This may be in large part due to the complications of separating sensory modalities experimentally, or in simpler terms, verifying cross-modal transfer has actually occurred. While the definition may be self-explanatory, the function of cross-modal transfer may be unclear. This concept suggests humans (and other species) take information from multiple sensory modalities and create a holistic, globally accessible version of objects/surroundings. This serves as a way for cognitive systems, in multiple species, to take information from different sensory modalities and convert them into a universal mental representation of those objects. Note the specific deviation from the term *mental image*, as cross-modal transfer goes outside of the visual domain, including auditory and haptic domains as well.

As previously mentioned, cross-modal transfer can be somewhat challenging to observe. Speaking generally, the typical formula for measuring this concept goes as follows: learn information in one modality, restrict the initial encoding modality, then test retention through a second, different modality. Dopjans, Wallraven, and Bulthoff (2009) examined this effect through the lens of visual and haptic face recognition. Facial recognition in the visual domain is a skill repeatedly practiced through most aspects of social life, while haptic facial recognition is a skill that receives little to no attention. The authors found haptic recognition performance that exceeded expectations, as well as good cross-modal transfer from both modalities. This concept of visual to haptic/tactile transfer extends outside of humans, as Solvi, Al-Khudhairy, and Chittka (2016) demonstrated a similar ability of object recognition within bumblebees. These findings suggest not only are mammals capable of producing universal representations of the world around them, but insects may also possess the same capabilities. Other mammals are capable of such transfer as well, as exemplified by multiple studies conducted on primates including chimpanzees and baboons. Martin-Malivel and Fagot (2001)

demonstrated cross-modal integration leading to conceptual categorizations with baboons. A similar ability was shown in chimpanzees by Savage-Rumbaugh, Sevcik, and Hopkins (1988), across a wider range of cross-modal transfer types. Schreurs and Kehoe (1987) assessed the degree of training required to elicit a cross-modal transfer within rabbits, finding that as few as two rounds of conditioning may be sufficient. There are limitations to this phenomenon, though, particularly involving auditory to visual transfer, as Lapid, Ulrich, and Rammsayer (2009) were unsuccessful in finding any evidence of a transfer from the auditory domain to the visual domain.

To understand the mechanisms involved in cross-modal transfer, it may be useful to examine the neural correlates proposed by this literature. Calvert (2001) conducted a review of functional neuroimaging suggesting specific roles for multiple areas, including the superior temporal sulcus, the inferior parietal sulcus, regions of the frontal cortex, the insula cortex, and the claustrum. Importantly, the specificity and networking of these regions relies upon the experimental methods used. However, there is a degree of consistency to be noted across a large body of the literature in this area. In one example, Hadjikhani and Roland (1998) examined regions involved in tactile and visual representations. Here, several of the aforementioned regions of the brain were highlighted in the transfer of tactile to visual (and vice versa), however, the right insula-claustrum was specifically highlighted for its supposed role in cross-modal matching. The claustrum's function as a sort of distribution center for multimodal cortical projections, as well as its PET activation during the study, led the researchers to believe it may play an important role in cross-modal transfer.

The implications of cross-modal transfer are somewhat broad. In regard to animal cognition, these findings seem to be very telling. Some of the aforementioned literature seems to suggest that animals, from large brain mammals to common insects, are capable of these cross-modal representations of objects in their brains. This suggests animals are capable of forming mental images and spatial representations of their surroundings. Expanding research along these lines could be very useful in providing insight into the

similarities between human and animal cognition. With regard to expanding the human cognition literature, there is still much to be found in confirming both the localization of cross-modal transfer, as well as validating the existence of cross-modal transfer across different domains.

There are limitations with some of the existing research. Specific to the findings involving neural correlates, there is often low statistical power/sample sizes, which is a problem not limited to, but noted especially in neuroimaging studies (Bossier et al. 2020). It is possible the variations in findings across these referenced studies could be due to a general lack of reproducibility. There are also slight variations in the specific regions activated during cross-modal activities. These variations may reflect the diversity of experimental paradigms used.

Future research ought to expand some of the previously mentioned literature. There is potential expansion into using neural networks and artificial intelligence to increase our understanding. For example, Albanie, Nagrani, Vedaldi, and Zisserman (2018) have used neural networks to label video data with emotional speech by facial recognition software. Overall, the literature on cross-modal transfer is expansive across both humans and animals, yet replications can provide more power to existing findings.

## Definition

Crossing over is exchange of genetic material between homologous chromosomes during meiosis stage.

## Crossing Over

Crossing over involves exchange of genetic material between homologous chromosomes (having same genes at the same loci, but possibly different alleles). The exchange of chromosome occurs during meiosis and can be visualized as chiasma that interlocks homologous chromosomes. This is visible in form of physical overlapping between chromosomes and works opposite to the polarizing forces of the meiotic spindle (protein structures that divide the genetic material in a cell) as shown in Fig. 1. Crossing over prevents premature segregation of homologous chromosomes during first meiotic cycle (Page and Hawley 2003). Problem or interruptions in crossing over may lead to abnormalities like gene linkage, nondisjunction of chromosomes, aneuploidy, etc. (Hassold et al. 2009). Low rates of crossover and abnormal patterns of crossover are known to be associated with infertility in multiple organisms (Koehler et al. 2002).

The genetic significance of crossing over is to create varying combinations of alleles and determining primary determinant of haplotype (genetic characters located on same chromosome) diversity within populations (Pritchard and Przeworski 2001). Also, crossover results in decoupling of highly fit alleles, and therefore can reduce strong association between alleles so as to facilitate natural selection (Hill and Robertson 1966).

The frequency of crossing over is quite dependent on multiple biological forces like

concentration of rate limiting enzymes involved in meiotic DNA repair, the strength of the mutagenic effect of recombination, and the rate at which recombination breaks up high fitness haplotypes. The recombination rates are also determined by essentiality of crossovers for chromosome segregation. Because of these varying factors the crossover rates are highly variable across mammals, plants, and animals. The closely related species of house mice may show differences in crossover rate by around 30% (Dumont 2017). Recombination arising due to crossover may be due to several contributing factors such as environmental exposures and involvement of individual genes (Chowdhury et al. 2009). Environmental factors include exposure to xenobiotic compounds (foreign chemical compounds) and various stress-causing agents (Vrooman et al. 2015) and various measures of stress (Singh et al. 2015). In case of diploid chromosomes, the chromosome architecture plays an important role in deciding recombination rate. A minimum of one crossover per chromosome is required for correct chromosome segregation. However, there are evidences suggesting at least one crossover per chromosome arm. The crossover analysis in voles, deer mice, shrews, and rhesus macaques reveal a high frequency of achiasmate chromosome (lacking chiasma in meiosis) arms undergoing crossing over (Dumont 2017). Besides genes and environment, the evolutionary changes in the organisms also play a crucial role in recombination rate and crossing over occurrence.

## Definition

Colors and color patterns that reduce the risk of an object being visually detected when it is potentially perceivable to an observer.

## Introduction

Avoiding detection by undesirable viewers is a key antipredator strategy, and the evolutionary solutions to this challenge are myriad. Crypsis – the use of color patterns to minimize the probability of detection – is the most prevalent form of visual camouflage and has served as an exemplar of adaptation since the inception of modern evolutionary biology (Poulton 1890). The seminal work of Abbott Thayer (1909) in *Concealing Coloration in the Animal Kingdom* and Hugh Cott (1940) in *Adaptive Coloration in Animals* lays the formal foundations for the study of crypsis, and camouflage more generally, which has since burgeoned into an active field of inquiry spanning biology, art, and technology (Behrens 2009).

## Mechanisms

The functions of cryptic color patterns have often been considered obvious, though a breadth of work continues to detail the subtle complexity of this mode of defense. Confusion surrounding the language used to describe such colors has complicated efforts, though recent calls to focus on the perceptual effects, rather than the superficial appearance, of color patterns, have proven fruitful. Stevens and Merilaita (2009) take a broad view of crypsis and summarize six principle mechanisms:

1. *Background matching* describes the use of color patterns that approximate the appearance of the broader viewing background (in color and/or brightness) and so allow an object to blend in to its surrounds.
2. *Self-shadow concealment* is achieved via countershading, wherein darker colors adorn an object's upper side and lighter colors cover its underside. This can obscure the presence of conspicuous shadows generated by directional light sources (typically the sun), which can reveal the location of otherwise inconspicuous objects.
3. *Obliterative shading* is also achieved via countershading, though here the ultimate effect is to destroy the three-dimensional form of an object by disrupting the lighting cues that underlie its perception.
4. *Disruptive coloration* relies on the use of conspicuous, contrasting markings to generate the illusion of false edges and boundaries, thereby impeding the detection and recognition of an object's "true" form.
5. *Flicker-fusion camouflage* is a dynamic form of cryptic coloration in which color patterns rely on motion-induced blurring for their background-matching, cryptic effect.
6. *Distractive markings* deflect the attention of a receiver away from identifying characteristics, such as the distinctive outlines of body regions, to prevent their detection.

These mechanisms are non-exclusive and are typically combined to achieve a more robust

cryptic effect. Self-shadow concealment and obliterative shading, for example, may draw on a similar counter-shaded appearance to simultaneously exploit the disruption of both an object's shadow and three-dimensional form (Rowland 2009). Similarly, disruptive coloration can be fruitfully combined with background matching to achieve "differential blending," wherein some components of a color pattern strongly contrast with viewing backgrounds while others are closely matched (Barry et al. 2015). This enhances the broader disruptive effect and can thus more efficiently obscure an object's true form.

## Cryptic Coloration in Art and Technology

Many of the principles that describe the efficacy of crypsis can also be found – and even trace their origins – to the visual arts. Abbott Thayer was himself an artist and regularly acknowledged the role of his artistic training in shaping his thinking on adaptive coloration (Behrens 2009). He was also quick to chide his contemporaries that lacked a similar appreciation, even suggesting that they were incapable of understanding the adaptive function of visual camouflage because it:

...can be interpreted only by painters. For it deals wholly in optical illusion, and this is the very gist of a painter's life. He is born with a sense of it; and, from his cradle to his grave, his eyes, wherever they turn, are unceasingly at work on it, – and his pictures live by it. What wonder then, if it was for him alone to discover that the very art he practices is at full – beyond the most delicate precision of human powers – on almost all animals? Thayer (1909, p. 3)

Thayer's work also directed efforts at improving the state of military camouflage during World War I, which has continued through to the present day. Cryptic patterns are now standard features of modern military uniforms, for example, and both disruptive and background-matching elements feature prominently on camouflage for vehicles and installations (Newark et al. 2002). As in the natural world, motion, shadowing, and surface texturing are enduring challenges to the effectiveness of cryptic coloration, as they can reveal the

presence of objects irrespective of their appearance. The development of radar has also rendered the use of visual camouflage largely irrelevant for larger structures, in the same way that an animal's crypsis may be broken by the use of different sensory modalities.

## Conclusion

Cryptic coloration is widespread form of visual camouflage in which color patterns are used to minimize the probability of visual detection by undesirable viewers. It has served as a key example of adaptation by natural selection, with far-reaching consequences across human domains of study.

## Definition

Cryptic female choice (CFC) is a postcopulatory sexual selection process that, through differences in the expression of female morphological,

behavioral, or physiological traits, results in paternity biases favoring males with particular characteristics over other ones.

## Sexual Selection During and After Copulation

Since Darwin (1871) and until the 1970s, sexual selection studies were focused on intrasexual and intersexual processes occurring prior to mating. Males would compete and woo females, and females would choose among the potential sexual partners and finally determine mating occurrence. Parker's pioneering work (Parker 1970) introduced the ideas that competition among males for the fertilization of eggs can continue after female mating acceptance and sexual selection can drive the evolution of male traits to increase their success in sperm competition. In 1983, Randy Thornhill introduces the concept of cryptic female choice that implies that sexual selection through female choice can also operate during and after mating. The term "cryptic" relates to its occurrence in the female, hidden from the male, and after the decision to accept mating (Eberhard 1996). Additionally, the word "cryptic" could refer to the fact that postcopulatory sexual selection through female choice remained unknown for evolutionary biologists until the 1980s. CFC caused a revolution in sexual selection studies, revaluing and highlighting the active and essential female role in determining the fate of male paternity success.

## Mechanisms of CFC

William Eberhard, in his milestone book "Female Control: Sexual selection by Cryptic Female Choice" (Eberhard 1996), performs an exhaustive review of the mechanisms known to occur in species with internal fertilization through which females can exercise CFC by changing their responses and consequently imposing paternity biases favoring one male over other one. Some of these morphological, behavioral, or physiological mechanisms are: permitting (or not)

penetration of male genitalia to reach the site of sperm storage, finishing mating prematurely, transporting sperm to sperm storage sites, nourishing sperm, dumping sperm, ovulating, producing eggs with more or less nutrients, aiding the male in producing and depositing mating plugs that lower the possibilities of female remating, aborting, among others (see Eberhard (1996) for a complete list). Females can base their decisions on male traits sensed prior to and/or during mating. Summarizing, for CFC to occur, females must mate – at least occasionally – with more than one male prior to brood production, and there must be differences in female sexual responses to particular male traits that affect his chances of paternity (Thornhill 1983; Eberhard 1996).

In several species distributed among a variety of animal orders, males continue courting females during mating (Eberhard 1996). Male copulatory courtship would have the function of stimulating the female, inducing her to favor that sexual partner by increasing his chances of paternity. Male copulatory courtship constitutes evidence of the occurrence of sexual selection through CFC in a species. We can also expect rapid evolutionary diversification in male genitalic and nongenitalic traits involved in sexual interactions in species in which CFC is a main driving evolutionary force (Eberhard 1996).

It is important to keep in mind that in the same system, sexual selection forces such as sperm competition, sexually antagonistic coevolution, and CFC are not excluding from one another and they can be acting at the same time, challenging the determination of the main selective force driving the sexual scenario of our study model.

## Mate Choice: Looking into the Future

Arthropods, and more specifically, insects and arachnids, have shown to be promissory models for studying postcopulatory sexual selection (Peretti and Aisenberg 2015). The possibility of modifying male contact structures and restricting female abilities to sense them, checking for the effects on female responses regarding male paternity, could be crucial for confirming CFC. This

requires elegant and simple experiments with fine-scaled observations of the sexual behavior of the study species.

Advances in technology regarding possibilities, such as individualizing sperm from different males, modifying male and/or female phenotypes in traits driven by sexual selection, and estimating reproductive costs for each sex, will help disentangle the effects of female- versus male-driven mechanisms while possibly adding new cases of CFC (Firman et al. 2017). Vertebrates offer a relatively understudied scenario with many questions to answer.

This section is focused on cryptic mate choice in females. The possibility of cryptic male choice (CMC) remains almost unexplored. CMC could be linked with sperm competition, for example, varying sperm allocation strategies according to female quality. An interesting case occurs in the soldier fly where males can control copulation duration according to female size: it is longer when males mate with larger, more fecund females (Barbosa 2011). In addition, in a scorpionfly species males in poor condition exert CMC by producing larger salivary masses – that function as nuptial gifts – in matings with more fecund females (Engqvist and Sauer 2001). Systems with sex role reversal (Gwynne 1991), in which females and males show nontraditional behavioral roles, offer outstanding opportunities to study the possibility of cryptic male choice.

Finally, copulatory communication or copulatory dialogues between the sexes regarding CFC have been scarcely studied (see Rodríguez (2015) for an update) and remain as interesting areas for future research. In this scenario of intersexual communication, modulations of behavioral units (e.g., in frequency or duration) associated with sperm transfer, sperm removal, external stimulation (e.g., by tapping or rubbing each other), and internal stimulation (e.g., with male genitalia) would be expected.

## Cuckoldry

Rachel M. James and Todd K. Shackelford  
Department of Psychology, Oakland University,  
Rochester, MI, USA

### Synonyms

Cuckoldry risk hypothesis; Paternity uncertainty;  
Sexual infidelity

### Definition

Female internal fertilization has posed the adaptive problem of cuckoldry, or being deceived into providing resources or investment in genetically unrelated offspring, for males across species. Cuckoldry is an adaptive problem for males because investing in a rival's offspring rather than one's own is reproductively devastating, especially for males of high-investing species. Consequently, males in species in which female internal fertilization occurs have evolved anti-cuckoldry tactics.

### Introduction

In externally fertilizing species, such as most species of fish, males can be certain of their paternity, and their paternal investment will not benefit a rival's offspring because external fertilization allows males to witness the fertilization of a female's eggs (Trivers 1985). Cuckoldry, or being deceived into providing investment into genetically unrelated offspring, is an adaptive problem that males face primarily in species in which fertilization occurs within the female, such as humans, cats, and reptiles. Although males may be cuckolded in externally fertilizing species (Jones et al. 2001), the likelihood of paternity uncertainty is lower and less consequential in terms of reproductive costs than for paternally investing males in species with internal fertilization. Internal fertilization affords females the certainty that they are the genetic parent of the offspring they produce. From an

evolutionary perspective, females benefit from internal fertilization in part because they can deceive males into providing paternal investment, such as provision of resources and physical protection, in offspring to whom they are not genetically related while producing these offspring with genes contributed by, for example, a genetically higher-quality male. In these circumstances, females may secure "good genes" from one male and investment from the cuckolded male. Cuckoldry thus can be reproductively beneficial for the female and the genetic sire of offspring, while it is extraordinarily costly and rarely beneficial for the cuckolded male.

### The Problem of Cuckoldry

Given the amount of time and resources males invest in females and their offspring, it can be reproductively devastating for a male to be deceived into allocating paternal investment to an offspring to whom he is not genetically related (Platek and Shackelford 2006). In species, such as humans, in which males provide nontrivial, and sometimes substantial, parental care, cuckoldry is especially reproductively costly. Specifically, when a female's egg is fertilized by another male, the cuckolded male will fail to have sired the resulting offspring and, moreover, will invest resources into a rival's offspring. In some instances, cuckoldry can be costly for *both* males and females. One study reported that sand goby (*Pomatoschistus minutus*) males may sneak to fertilize eggs, thereby preventing the desired male from achieving fertilization and disrupting female-driven sexual selection processes (Jones et al. 2001).

### Solutions to the Problem of Cuckoldry

To address or avoid the costs associated with cuckoldry, males of many species have evolved anti-cuckoldry tactics that may lower the risk of cuckoldry. For example, male tropical house wrens (*Troglodytes aedon*) may be able to identify paternity markers in eggs laid by females (Freed 1987). Specifically, Freed (1987) examined male destruction of eggs laid after the appearance of new males, finding that resident males appear to be able to identify paternity by behaving differently toward eggs introduced after the new males appeared – in some cases, destroying the eggs if

the new male was introduced during the female's fertile period. However, when resident males spent more time with the female during her fertile phase, they were less likely to engage in egg destruction, suggesting that greater resident male vigilance of the female lowers the risk of cuckoldry. Thus, mate guarding, or occupying the female's time and engaging in surveillance of her sexual behavior, is an anti-cuckoldry strategy that males use to lower the likelihood that the female will copulate with other males, thereby preventing cuckoldry. By entering long-term relationships or pair-bonds with females, males can guard the female more frequently or vigilantly and have more opportunities to copulate with her, increasing the likelihood that the offspring she produces are not sired by rival males (Strassmann 1981). Mate guarding is often costly in terms of time and resources, however.

Human males also use a variety of mate retention tactics, or behaviors that discourage a partner from engaging in sexual infidelity or leaving the relationship, to reduce the risk of cuckoldry (Buss 2002). These behaviors range from vigilance over a female partner's whereabouts to physical or sexual violence against the female. For example, Kaighobadi et al. (2008) reported that accusations of female infidelity predicted men's violence against their partner. Because female infidelity sometimes results in cuckoldry, men sometimes use violence against their partner to discourage them from committing infidelity.

Males may also sometimes *engage* in sperm competition, a process in which sperm from two or more males compete to achieve fertilization of the female's egg, to reduce the risk of cuckoldry. In humans, males engage in more frequent in-pair copulation and mate guarding behavior when they spend less time with their partner since the couple last copulated (Shackelford et al. 2006). Males that are unable to guard a female partner during her fertile phase risk cuckoldry. In instances of greater time spent apart since last copulation, males increase in-pair copulation frequency to engage in sperm competition, reducing the likelihood of conception by a rival male. However, in some circumstances, males engage in sexual coercion to increase in-pair copulation frequency. The

cuckoldry risk hypothesis for sexual coercion suggests that sexual coercion is a male tactic used to reduce paternity uncertainty (Camilleri and Quinsey 2009). Specifically, when a male's perceived risk of partner sexual infidelity (and consequent cuckoldry) is higher, they are more likely to sexually coerce their partner, suggesting that *engaging* in sperm competition via coerced intercourse may decrease cuckoldry risk. An additional study investigating 26 species of birds found that males copulated more frequently if the risk of sperm competition was higher, indicating that birds engage in frequent copulation to lower the risk of paternity uncertainty by engaging in sperm competition (Møller and Birkhead 1991).

## Conclusion

Female internal fertilization presents the adaptive problem of cuckoldry for paternally investing males, whereas females may reproductively benefit from internal fertilization by deceiving males into providing care for offspring sired by, for example, genetically superior males. Cuckoldry is an adaptive problem for males because cuckoldry thwarts the male from producing his own genetic offspring, thereby failing reproductively, and causes him to squander his time, resources, and investment in a rival's offspring. As such, males have evolved anti-cuckoldry tactics to lower the risk of cuckoldry, including mate guarding, mate retention tactics, and tactics that motivate participation in sperm competition.

USA

## Synonyms

Coevolution; Egg rejection; Host-parasite interactions; Incubation behavior; Mimicry; Nests; Parental care

## Definition

Cuckoos eliminate the energy demands of rearing offspring by laying eggs in the nest of another bird species, thereby revoking all care of hatchlings.

## Introduction

In order to fledge a clutch successfully, most birds' parental responsibilities are energy exhaustive. First, they must build a nest; then the eggs must be cared for by continual incubation. Hatchlings require continuous feeding and protection. Cuckoos (Cuculidae spp.) mitigate the energy expenditure associated with rearing hatchlings through obligate brood parasitism in which the female lays her eggs in the nest of another specific host bird species (i.e., magpies, weaver birds, bishop birds, wrens) (Langmore 2013). After laying her eggs, she removes one or more of the host bird's eggs in order to make room for her offspring to thrive and to improve incubation efficiency (Langmore 2013). After her eggs are laid, she revokes all care of her offspring, allowing the host family to adopt her eggs and offspring instead (Langmore 2013). Only about 1% of all bird species exhibit this unique behavior (Sánchez-Martínez et al. 2017).

Sixty-four of the 149 species of Cuculidae (heretofore referred to as “cuckoos”) are obligate brood parasites, laying their eggs in the nests of other species of birds (Krüger and Pauli 2017). Cuckoos lay smaller eggs relative to their host, live in open and less productive foraging habitats, are migratory, and have a large breeding range (Krüger and Davies 2002). In North America, there are three species of cuckoos: yellow-billed cuckoo (*Coccyzus americanus*), black-billed cuckoo (*Coccyzus erythrophthalmus*), and mangrove cuckoo (*Coccyzus minor*). North American cuckoos are insectivores, and their foraging is enhanced by a slender, long-tailed body of about 12 inches and a wingspan of only 17–18 inches, enabling them to graze on caterpillars in dense shrubbery (Sibley 2000). Australia, Asia, Africa, and Europe boast an impressive 54 species of cuckoos, belonging to 12 genera. Australia is

home to the most diverse group of parasitic cuckoos in the world, which all parasitize more than one host (Langmore 2013). Europe has only four species of cuckoos, all of which exhibit brood parasitic nesting, typically within the nests of magpies. These birds are somewhat larger than their North American kin, ranging in length from 12 to 15 inches, exhibiting little sexual dimorphism (Peterson et al. 1993). Finally, South America has only five species of cuckoos that are brood parasites, all dwelling within the Amazon (Sánchez-Martínez et al. 2017).

## Strategies for Brood Parasitism

Cuckoos tend to parasitize birds that are very different from their own kind. To be able to successfully compete with their hosts, they have developed some very interesting strategies: egg mimicry (thickened egg shells, color matching of the egg to the nest and to the host's eggs, smaller egg size), destroying the nests of other birds during late incubation, the eviction of host eggs by hatchling cuckoos, faster egg laying and hatching times than their hosts, and luring the host away. All these strategies reduce the likelihood that the cuckoo eggs will be rejected by the host.

### Egg Mimicry

The shining bronze cuckoo (*Chrysococcyx lucidus*) produces smaller eggs and eggs colored to the nest of its host, the Australian grey fantail (*Rhipidura albiscapa*), which camouflages the hosts' ability to see the parasitic eggs (Attenborough 1998). The African diderik cuckoo (*Chrysococcyx caprius*) employs a similar approach of egg mimicry. However, this species benefits from various hosts. Thus, each female diderik produces polymorphic egg types (i.e., each female lays a different color egg to match its host), but it is only able to lay one color morph of egg, so the female cuckoos choose the species of bird to parasitize that most closely resemble the type of egg they lay (Attenborough 1998). For instance, if the female diderik cuckoo lays blue eggs, then she will lay her egg in the southern red bishop (*Euplectes orix*) bird's nest (Attenborough 1998). If she lays a speckled

white pattern, then she will choose the southern masked weaver (*Ploceus velatus*) bird's nests (Attenborough 1998). A similar strategy can be observed in the Southern Australian brush cuckoo (*Cacomantis variolosus*), which also produces polymorphic egg types for all three of their main hosts: the grey fantail (*Rhipidura albiscapa*), the scarlet robin (*Petroica boodang*), and the leaden flycatcher (*Myiagra rubecula*) (Langmore 2013). Sometimes in egg mimicry, as seen in the brush cuckoo, the color differences can be so subtle that it is undetectable to the human eye (Langmore 2013).

### Distraction

Another strategy proven successful in the Asian koel cuckoo (*Eudynamis scolopaceus*) is where the male cuckoo will lure the host from its nest so that the female cuckoo can access the host's nest and lay her eggs without detection (Langmore 2013). This behavior is significant in that it models both coordination and planning between the male and female cuckoo, both considered to be traits of advanced cognition.

### Rapid Egg Laying and Development

Cuckoos lay their eggs within 1.5–5.3 seconds (Langmore 2013). This operates in two ways: it prevents abandonment of the cuckoo eggs and nest by reducing the chances of detection and it also reduces the chance of the host bird defending its nest with mobbing or other defensive strategies (Langmore 2013). Cuckoo eggs also grow and hatch at a rate faster than the host eggs, allowing the cuckoo chick to grow before the host chick even hatches (Stevens 2013). Being larger than its host, the cuckoo chick is able to remove its competition from the nest. Even before the cuckoo chicks opens their eyes, some cuckoo chicks evict the host eggs from the nests by balancing the eggs on their back and heaving the eggs off the side of the nest one at a time (Stevens 2013). The cuckoo chick grows so rapidly that it often outgrows its host parent before it reaches the fledgling stage (Stevens 2013). If the host chicks live to fledgling age, the cuckoo chick will again attempt to eject its competitors from the nest. The cuckoo chick performs this action to prevent rejection from the host parents due to abandonment of the

nest (Sánchez-Martínez et al. 2017). Abandonment of the nest can happen either due to recognition of differences present in the nest, such as having more than one species present or too many eggs or hatchlings present, not necessarily species differentiation (Sánchez-Martínez et al. 2017). Cuckoo chicks are also more aggressive than their competitive chicks, often biting and pecking the skulls and backs of the other chicks in the nest (Sánchez-Martínez et al. 2017).

### Destruction of Host Nests

In destroying the host's nest late in the incubation period, hosts are forced to create a new nest with very little time left in the season to successfully hatch and fledge a clutch. However, because the cuckoo has evolved rapid embryonic and hatching development relative to other species, the parasitic offspring is more likely to survive than the hosts' offspring (Langmore 2013). The shining bronze-cuckoo (*Chrysococcyx lucidus*), fan-tailed cuckoo (*Cacomantis flabelliformis*), and Horsfield's bronze-cuckoo (*Chrysococcyx basalis*) all employ this strategy (Langmore 2013).

### Offspring Mimicry

Cuckoo chicks often look completely different than their hosts' chicks, but chick mimicry has not evolved because the hosts do not typically reject the chicks in their nests even if they look different from their own (Langmore 2013). However, the cuckoo chicks have evolved to mimic the calls and cries of their hosts, which are innate cues for the adult birds to respond with care behaviors (Langmore 2013). They use these mimicked cries to acquire more food than their brood mates, if any are left in the nest with them, by crying with more exaggeration, thus obtaining more of the host parents' attention and food (Stevens 2013). The cuckoo chick must mimic the calls and cries at an exaggerated rate to compensate for its lack of a visual mouth display (i.e., opening the mouth to present an array of colors inside the mouth) (Kilner and Davies 1999), because in the chicks of the host species, the visual mouth display is brightly colored for parental signalment of food deprivation (Kilner and Davies 1998).

### Costs of Parasitism

Parasitism comes at a great cost to the host. This cost can include the death of the host's chicks, as well as the host parents. With the exaggerated mimicry cries and the larger size of the cuckoo chick, the host parents are often forced to forage for extra food (Stevens 2013).

Because of the increased burden of food and incubation activity for larger chicks, the burden of the host bird raising the cuckoo chick is about twice that of the host bird raising its own chick, especially within the first week post-hatch (Sánchez-Martínez et al. 2017). In contrast, the cuckoo needs only about half the reproductive energy of the host to achieve its reproductive success (Krüger and Davies 2002).

### Parasitized Host Mitigation

Cuckoos are elusive birds, as hosts are more likely to reject the foreign eggs if they have recently seen a cuckoo (Stevens 2013). Upon observation of a cuckoo by the host, most species will mob the cuckoo and emit alarm calls which direct other host birds to join in the cuckoo mobbing (Stevens 2013).

Masked weaver bird species of Africa, which have evolved to lay eggs of multiple different colors (i.e., white, blue, and speckled), to diminish cuckoo egg mimicry and have also designed their nests to prevent parasitism (Attenborough 1998). First, their nest is globular shaped with only one entrance and exit combined. This way, the female diderik cuckoo is unable to see what color the eggs are in the nest, so she must enter multiple nests until she finds the right color eggs present for the eggs she has evolved to lay (Attenborough 1998). Secondly, the entrance and exit to this globular-shaped nest are very small, so small, that female diderik cuckoos often get stuck trying to enter the nest and die (Attenborough 1998).

Other host species abandon their nests when more eggs than their original clutch size are observed, implying an understanding of numerocity (Langmore 2013). Others abandon their nests when one or two eggs hatch significantly

sooner than the other eggs in their nest (Langmore 2013). This strategy can be observed in the fairy wrens of Australia as a defensive strategy used to combat the brood parasitism of the Horsfield's bronze-cuckoo (Langmore et al. 2003).

Some host birds have convergently evolved a tolerance response rather than direct action. One example can be seen in the Corvidae species of the Eurasian magpie (*Pica pica*). The Eurasian magpie has evolved a larger brain size in comparison to other non-Corvids and has the cognitive ability of self-recognition and episodic memory (Prior et al. 2008). These cognitive abilities are linked to a higher development of social intelligence (Prior et al. 2008). This convergently evolved tolerance response is apparent in the Eurasian magpie's nesting behavior of co-raising the great spotted cuckoo's (*Clamator glandarius*) eggs and offspring with their own, rather than emitting the energy to eject the eggs from their nest or rebuild their destroyed nests (Soler et al. 2011). Through coevolution, the Eurasian magpies have evolved to produce a larger clutch of eggs, allowing some of their offspring to grow up with the great spotted cuckoo's (Soler et al. 2011). The evolutionary selection pressures are much less when tolerance is adapted competition with brood parasites.

## Evolution of Brood Parasitism

Brood parasitism has a direct linear correlation with habitat shift to open space, change in diet, increase of migration length, increase of breeding range, decrease in population, and decrease in egg size and an indirect correlation with a shortened breeding season (Krüger and Davies 2002). Cuckoos exhibit a wide range of these evolved brood parasitic adaptations, which have been shown to evolve with the host's defenses. Cuckoos likely evolved the ability to lay a larger clutch size after brood parasitism evolved, because they were freed from the energetic demands of incubating, caring for, and protecting hatchlings (Krüger and Davies 2002). Coevolution is a naturally occurring event where two or more species evolve as a result of adaptations and counteradaptations (Gandhi 2019). Brood

parasitism has been widely studied because it is an excellent model for coevolution in determining whether these parasites have a negative impact on their hosts (Sánchez-Martínez et al. 2017).

Most commonly seen throughout the coevolution of brood parasitism is the model in which the parasite chooses a host target, and the host suffers the cost for the parasite (Stevens 2013). The host then evolves a way to recognize the cause of their extra cost, such as recognition of foreign eggs, and then removes them from their nests. Next the parasite evolves a way to perform better mimicry of the host's eggs to avoid the host's detection, which then leads to the host evolving better detection for rejection. The cycle will continue, with the host and the parasite each getting the upper hand on each other sequentially (Stevens 2013).

There are several proposed theories as to why cuckoos evolved obligate brood parasitism, although little effort has been made to explain these strategies. First, the female cuckoos find themselves with the inability to create a nest, either due to lack of location or lack of nesting materials (Krüger and Pauli 2017). Second, the female cuckoos find themselves not able to care for their young, perhaps due to lack of food supply (Krüger and Pauli 2017). Third, their nesting sites are destroyed either due to inclement weather or predation (Krüger and Pauli 2017).

## Conclusion

Understanding cuckoo brood parasitism will require additional research, as many stages of their parasitism are still in need of classification. These examples highlight the importance of coevolution and brood parasitism and the highly unique and specialized behavior of cuckoos all over the world.

## Introduction

The term “cultural transmission” is widely and often imprecisely used in the scientific literature to refer to various forms and outcomes of social learning. This entry considers cultural transmission to refer to the specific forms of social transmission where knowledge is passed between individuals, through some form of social learning, resulting in persistent increases in behavioral homogeneity in a population or group. In this way, cultural transmission allows different populations or groups of animals to show distinct differences in behavior. As described in the social learning section (“▶ [Social Learning](#)”), social transmission occurs when the performance of a behavior by one individual (directly or indirectly) causes a lasting influence on the rate at which a second individual acquires and or performs that same behavior. While social transmission can

allow behaviors or knowledge to persist at individual level, only those behaviors or knowledge which persist long enough to become common within a group or population over time or across generations can properly be called cultural. By taking this perspective, this article is consistent with a key recent text in the field (Hoppitt and Laland 2013).

Transmission of behaviors, traits, or knowledge between individual allows for rapid adaptation to changing or novel situations (“► Copying”). This affords individuals, in most cases, lower cost alternatives to trial and error (or “asocial”) learning and allows animals to learn more rapidly, especially in group situations. In many cases, the types of things that are transmitted through a group are essential drivers of fitness at the individual level, and cultural transmission allows this information to spread relatively quickly through whole groups of animals with consequent effects on individual and, potentially, group survival, leading subsequently to potentially important evolutionary effects. Like social transmission, cultural transmission can play an important role in a wide variety of behavioral domains that are beneficial or essential to animals, including mate choice, breeding site choice, foraging decisions, predator avoidance, and migration routes (although it is important to note that it can also lead to the acquisition of maladaptive behavior). However, cultural transmission specifically can lead to distinct group level differences in behavior and behavioral repertoires in animals.

An early and archetypal empirical example of cultural transmission comes from studies of birdsong learning. For example, juvenile white-crowned sparrows, *Zonotrichia leucophrys*, acquire a specific song type or “dialect” in their first 100 days of life, and this is heavily influenced by the song that they hear sung by adults, often their father or a close relative, during that time period (Marler and Tamura 1964). After this learning period, their song type does not change with experiences of other song types, and this mechanism allows successive generations of sparrows to retain dialects that differ between regions. Later studies of cultural transmission of bird song,

in this case on Darwin’s finches (*Geospiza* sp.) from the Galapagos Island of Daphne Major, highlight the importance of the cultural transmission as an evolutionary force. Long-term studies of the finches show that song is an important factor in species recognition and mate choice, and female finches use song to choose reproductive partners, selecting males that sound different to their paternal song while avoiding hetero-specific song types (Grant and Grant 1996).

Evidence for cultural transmission has since been found in a wide variety of other species from insects (Alem et al. 2016) to whales (Allen et al. 2013). It is a highly active area of current research and new evidence continues to be produced, helping us better understand how animals make behavioral decisions in the wild, such as the tendency to conform to more frequently observed variants of a behavior (Aplin et al. 2015).

This article focuses on cultural transmission in nonhuman animals with little focus on human cultural transmission; however, it must be noted that *Homo sapiens*, as the animal with the most complex form of culture and cultural transmission, is an important reference point. Many animal studies are undertaken with the underlying comparative goal better understanding the evolution human culture and cultural transmission, even though better understanding of the subject animals themselves is a happy proximate outcome. It can of course work both ways, and studies of human cultural transmission, being the most obvious, relatable and also sophisticated form of cultural transmission, can help us understand cultural transmission in other animals. This is perhaps made more important given the increase, or at least perceived increase, in the rate of cultural evolution in human cultures, with the technically enabled abilities for global scale social connections and rapid spread of information working at speeds well ahead of other processes of biological change.

This article will discuss the pathways through which cultural transmission operates. Given that many of the underlying mechanisms and processes of cultural transmission are common to the closely related articles on social learning and culture, there will be some inevitable overlap between this and other articles. Here we will

focus on the question of why cultural transmission is an important topic of study in nonhumans. In addition there will be some discussion of the more prominent current debates concerning cultural transmission or to which further studies of cultural transmission may contribute.

## The Importance of Studying Cultural Transmission

Culture may be considered a pinnacle of social behavior and one of the key characteristics that separate humans from other animals (“► [Culture](#)”). Cultural transmission is a fundamental part of the evolution, development, and maintenance of culture, and thus a key explainer of behavioral variation in humans and nonhumans (Mesoudi and Whiten 2008). There is some disagreement as to what constitutes culture transmission, in the philosophical and psychological fields especially, as explored in Acerbi and Mesoudi (2015) and Sterelny (2017). However there is overall agreement that cultural transmission can be said to result from the combination of learning mechanisms and attentional biases through which cultural information comes to be shared between individuals such that they come to behave more like each other, in a persistent way, sometimes spanning generations (Acerbi and Mesoudi 2015; Henrich 2001; Mesoudi et al. 2006). Cultural transmission is therefore of great interest, as studying it reveals how animals in many species come to behave as they do, as well as provide clues to the evolution of human culture, enabling us to discern the differences between human and other animal cultures, and reveal how human and other animal cultures developed and continue to develop.

Cultural transmission plays a role along with ecology, geography, and genetics in shaping differences between populations and species. Behavioral modification through social and cultural transmission can allow animals to more rapidly adapt to a changing environment than genetic processes and given the challenges and stressors that animals are facing across the globe, due to climate change, habitat modification, overexploitation, and associated regional

environmental changes, understanding the role of cultural transmission in how animals adapt to changing conditions is becoming increasingly important. Understanding the propagation and persistence of learnt behaviors through animal populations, as well as why some social transmission becomes cultural or not, may help us to better manage or mitigate some of these effects.

The spread of knowledge about novel predators or novel habitats through a group may be even more important as such events become more commonly experienced by species as range shifts occur in a response to climate change or other large scale environmental perturbations. One example of cultural transmission of a new behavior comes from the transmission of a novel foraging behavior – lobtail feeding – in humpback whales, *Megaptera novaeangliae*, in the Gulf of Maine (Weinrich et al. 1992). Here the innovation and transmission of a modified version of bubble feeding, where whales slap the water with their tail prior to performing the more widespread traditional bubble feeding technique, may partially be explained by a change in the primary prey type. Lobtail feeding appears to have developed with a rise in the number of a specific prey fish, the sand lance, *Ammodytes americanus*, while more traditional feeding behaviors of these whales are associated with Atlantic herring, *Clupea harengus*. However, cultural transmission was shown to be key to its pattern of spread through the population (Allen et al. 2013).

Knowledge of and responses to novel predators may also spread through a population through cultural transmission. For example, blackbird, *Turdus merula*, mobbing behavior by experienced birds appears to promote learning in naive birds which can then learn to exhibit appropriate responses to these predators. When experienced, trained, birds mobbed an otherwise innocuous object, it induced naive conspecifics to mob those same objects when exposed to them in the absence of trained birds, and this mobbing behavior persisted over time (Curio et al. 1978). The importance of cultural transmission in an ecological setting is further illustrated by the rapid spread of information about prey cues and prey palatability through a population of predators. One such

example is the case of fringe-lipped bats, *Trachops cirrhosus*, learning to respond to a potentially dangerous novel prey. This species can use the acoustic calls of their frog prey to determine palatability, and social learning allows them to more quickly learn to differentiate between frog species. The bats learn to associate the calls of poisonous toad species, and avoid them, far more quickly when able to learn from an experienced demonstrator than when only able to learn by trial and error (Page and Ryan 2006). The study also provided some, albeit limited, evidence that the prey palatability could be spread by cultural transmission, as prey preferences were passed from bat to bat along a transmission chain suggesting that this knowledge may spread through a bat population. These examples show the important role cultural transmission can play in the spread of knowledge and development of group-wide responses to changes or potential danger in a changing environment.

However, these same processes that allow beneficial cultural information to spread through a community of animals relatively quickly can also create behavioral inertia, a resistance to change that can have potentially maladaptive consequences. An example of the consequences of the development of such inflexible transmission comes from studies of guppies, *Poecilia reticulata*, which were shown to develop sub-optimal route preferences to foraging areas. These route preferences persisted over several experimental generations, developed as individual guppies in a transmission chain followed routes based on following individuals that had been trained to develop specific and circuitous routes (Laland and Williams 1998).

Beyond enabling rapid adaptation and spreading of knowledge through a group, cultural transmission may work at a more fundamental biological level. Working in tandem with genetic transmission, cultural transmission is considered an evolutionary driver in “dual inheritance” theory, the idea that genes and culture interact and influence each other. As suggested by the bird song examples in the preceding section, this theory gives a framework for understanding how cultural transmission can, for example, help to

shape and/or maintain species and speciation. Essentially, behavioral variation caused by cultural transmission can alter selective regimes within a population, generating selection at loci whose products relate to the trait in question. Some of the best evidence for this in nonhumans (in humans it is abundant) comes from work on killer whales, *Orcinus orca*, groups of which have distinct “ecotypes” with specific learned prey preferences and hunting strategies, with some groups specializing on fish and others on sea mammals or other prey groups. Groups of killer whales from different ecotypes may be sympatric but will remain consistently different in their feeding behavior. Foote et al. (2016) showed that these groups were genetically distinct, and most separated by differences in genes related to the metabolism of different proteins more commonly associated with different prey types, suggesting that cultural differences between groups may drive genetic differences, leading to incipient speciation. Likewise, recent evidence in birds suggests that the evolution of cultural units over generations of cultural transmission can speed up the process of speciation (Mason et al. 2017).

## Key Debates About Cultural Transmission

The study of cultural transmission is central to a number of key ongoing debates in the field of cultural evolution. One concerns the differences between animal and human culture, where there is disagreement about how to define and delineate different forms of culture.

### What Social Learning Mechanisms Are Required for Cultural Transmission

Some authors place an emphasis on the types of social learning required for, or considered necessary, to lead to cultural transmission and thus culture. In these arguments only certain social learning mechanisms with high fidelity of information transfer such as ► [imitation](#) or ► [teaching](#) are thought to be capable of supporting cultural transmission and that the ability to use these social learning mechanisms may be at least part of what

makes human culture unique (Tomasello et al. 1993). Similarly, specific animal taxa may be considered capable of developing culture and while other species that use lower fidelity mechanisms of social learning cannot sustain the transmission of behaviors or knowledge through generations. This debate is made more pertinent given recent empirical support for the idea that cultural transmission can occur without the use of high-fidelity mechanisms of social learning. For example, human participants in groups where teaching and imitation were inhibited were still able to improve the performance of a design over successive generations of participants (Caldwell and Millen 2009). Certainly, there is some evidence that animals can develop what appear to be traditions using apparently low fidelity social learning mechanisms. The transmission of an alternate foraging technique, nectar robbing, by bumble bees, *Bombus terrestris*, provides one example. Bumble bees can collect nectar, by biting through the base of the flower rather than collecting nectar in the traditional manner, and this behavior was shown to be transmitted through social learning mechanisms where naive individual bumble bees were more likely to become robbers after being exposed to holes made by previous individuals, as a form of indirect copying (Leadbeater and Chittka 2008). The bumble bees did not need to observe a robbing bee to learn the technique and were therefore not using any of the social learning mechanisms regarded as sophisticated or high fidelity. It is important to point out that although the robbing technique was shown to allow transmission through a group of bees, it did not show cultural transmission as defined here, and merely that transmission of a behavior through indirect observation may be possible.

A classic example of the problems in identifying the types of mechanisms used in social and cultural transmission is the case of the transmission of milk bottle opening technique. In the early 1920s, people noticed that certain populations of blue tits, *Cyanistes caeruleus*, had begun using a new foraging behavior where they would open the tops of milk bottles and drink the cream from. This behavior spread rapidly through British and

European blue tit populations using a transmission process which was initially proposed to be based on a relatively simple social learning mechanism in conjunction with repeated inventions of similar techniques, within a similar time period in separate populations (Sherry and Galef 1984). However, the actual mechanisms at play are still indefinite and recent studies suggest that they may be more sophisticated than those originally proposed (Aplin et al. 2013).

### Are Nonhuman Animals Capable of Cumulative Culture?

The idea that humans are uniquely able to increase performance or innovate on learnt behaviors over generations, through the “ratchet effect-” like effect of cumulative cultural evolution (“► [Cumulative Culture](#)”), may be changing. Recent evidence suggests that animals can progressively increase the performance and efficiency of behaviors spread through cultural transmission (Sasaki and Biro 2017). In their study, homing pigeons developed modified and more efficient routes over successive experimental generations. However, there is no question of these animals developing through this process a solution so complex no individual could themselves invent it in their own lifetime – considered by some to be the key diagnostic of human cumulative culture.

### What Are the Other Key Factors Involved in Cultural Transmission?

While the mechanism(s) used in transmission between individuals within a group may play an important role in development of cultural transmission, it is not the only important parameter. Theoretical work has suggested that while high-fidelity information transfer is important in establishing cultural transmission of a new behavior, the stability of that behavior within a group may depend on other factors. Social learning and thus cultural transmission can depend on characteristics of naive (learner) individuals and or those of the experienced (demonstrator) individual, as well as a host of other ecological and psychological factors that have the potential to contribute to the stability and, thus, existence of animal culture (Claidière and Sperber 2009).

## What Is Transmitted During Cultural Transmission?

One key point of current debate hinges on the fact that unlike the physical transmission of genetic material between generations in biological evolution, cultural transmission does not always transmit things with obvious tangible properties (the exception being material culture), and there is ongoing debate as to how information is transmitted between individuals within a population (Sterelny 2017). The properties of what is transmitted can be ephemeral, biased, and/or modified during the process through which an individual learns, forgets, and relearns (Strimling et al. 2009). Given that transmission may be modified by both the sender and receiver, debate arises as to how cultural transmission operates. Are whole cultural units transmitted as replicated representations (or “memes”) of, for example, a specific behavior or are transmitted units instead reconstructed following sensory input of that behavior. Barkow et al. (2012) highlight the key point of the dispute by pointing out that individuals are not passive recipients of the cultural information. Individuals may consciously or unconsciously choose between sources of information and may edit that information in a dynamic process, and it can be difficult to discern between these differences. Any particular suite of behavioral traits, common among a majority of individuals within a population, may be the result of cultural editing processes operating at the individual level within that population converging on very similar behavioral traits or the result of transmission of those traits as a whole with little to no modification at the individual level. This is further complicated by the fact that different domains of information can be involved and the extent to which these domains are processed differently by the brain are subject to broad range of factors such as age, sex, and species.

Future studies into the social learning mechanisms capable of supporting and processes affecting cultural transmission may help to identify and further disentangle the differences and similarities in animal and human cultures and can help to solve these and other debates.

## Pathways for Cultural Transmission

Cultural transmission operates at the individual level using social learning mechanisms, but when aggregated can have population level consequences. The specific context and concurrent social environment can play an important part in affecting when an individual decides to learn (or copy) a specific behavior and/or who an individual learns from. Theoretical models have shown that indiscriminate social learning is not necessarily adaptive (Giraldeau et al. 2002), that in most cases naive animals should be influenced by several factors, and learning may be affected by specific changes in their environment, social or otherwise, and/or ontogenetic stage.

Cultural transmission as an inherently social process can be influenced by a number of social factors such as group size, and proportion of knowledgeable individuals can affect transmission of knowledge through a group. For example, in groups of pigeons, *Columba livia*, exposed to a new behavior, groups with a greater number of knowledgeable individuals had increased rates of transmission, while more naive individuals in a group reduced the speed of transmission (Lefebvre and Giraldeau 1994). These factors can play a role in group-wide transmission across generations, and species or individuals may develop or follow what are termed social learning strategies, which govern the decisions about “when” to learn, or “who” to learn from (Rendell et al. 2011). These strategies (such as “Who strategies” and “When strategies” described below) can in turn affect what is or is not passed through cultural transmission to other members of a group.

## Social Learning Strategies Thought to Influence Cultural Transmission

“Who” strategies can have a strong effect by biasing social learning through specific pathways. Many animals have been shown to use different social cues in learning from specific individuals, for example, individuals may favor copying from experienced individuals. Nine spine sticklebacks, *Pungitius pungitius*, have been shown to follow a “copy the larger” strategy where males prefer to copy behaviors and feeding choices of larger

males than smaller ones (Duffy et al. 2009), and domestic hens, *Gallus gallus domesticus*, use a similar strategy where hens will copy from those of higher rank in a social hierarchy (Nicol and Pope 1999). Many of these strategies can be considered proxies for learning from more successful individuals, which is suggested by theoretical models as a reliable route for long-term success (Mesoudi 2008). Although there are many examples of “who” strategies in social learning studies, there are fewer examples of these strategies working in cultural transmission pathways. This may be attributed to the relative difficulty in collecting longitudinal data of populations with cultural transmission. Explicit evidence of “who strategies” being used in cultural transmission pathways are therefore limited but some of the best evidence comes from songbird studies such as the Galapagos finches, where males tend to learn from and sing songs very similar to their fathers (Grant and Grant 1996). Similarly, “when” strategies allow individuals to make adaptive, context-dependent decisions. Choosing when to use an observed behavior or whether to copy a particular behavior at all can have important consequences for cultural transmission. One example of this type of strategy in a social learning context is the “copy-when-asocial-learning-is-costly” strategy exhibited by minnows, *Phoxinus phoxinus*, individuals of which use public information more often than asocial information when there is higher (simulated) predation risk (Webster and Laland 2008). Social learning strategies can therefore affect cultural transmission in so far as making certain behaviors or knowledge more likely to be transmitted, depending on the context within which that behavior is most commonly expressed and which individuals are doing the expressing.

### Transmission Pathways Through Populations

A key feature that crucially affects the way that cultural transmission may or may not interact with evolutionary processes is the relationship between paths of cultural transmission and demographic generations. Vertical transmission, easily understood from a human perspective, is where cultural transmission flows from parent to offspring. Cultural units are passed between

generations of individuals from one or both parents to offspring. As a classic example, in certain groups of bottlenose dolphins, *Tursiops* sp, female dolphins pass on the use of sponges as a tool for foraging on the substrate to their daughters (Krützen et al. 2005), and in many bird species, song is transmitted across generations from father to son (Mason et al. 2017). Horizontal transmission is a less focused pathway, with transmission propagating between members of a single generation, and can occur between unrelated individuals. For example male humpback whales sing very similar versions of particular song during the breeding season, and this song spreads through a population from male to male (Garland et al. 2011). Finally, oblique transmission occurs across generations from older to younger generations but where the demonstrators/models from which the younger individuals acquire their behavior are not their parents. An example here comes from roof rats, *Rattus rattus*, where pups given the opportunity to learn from un-related adults had significantly higher preferences for food eaten by those adults than those rats that had similar opportunities to learn from rats of the same age (horizontal transmission) (Chou et al. 2000).

Cultural transmission is not necessarily restricted to occur within species. Interspecies transmission is another pathway by which cultural transmission occurs and may act along any of the three pathways described above but across different species. A striking example comes from a study of cross-fostering experiments in wild birds which revealed that cultural transmission is involved in the development of behaviors long assumed to be innate. In the study, blue and great tit chicks were switched from their respective nests and thus were raised by parents of the alternate species. Blue tit chicks fostered by great tit parents learnt to use foraging sites and techniques normally specific to great tits and vice versa, and this niche-swap persisted for the life of the birds (Slagsvold and Wiebe 2011).

Limits to cultural transmission, across species and or within groups, will be revealed with further study of the parameters of transmission pathways. Exploring these pathways in different species and across different contexts will aid in the

understanding of how cultural transmission works to effect change over generations.

## Summary

When social learning results in effective and persistent transmission of a behavioral trait or knowledge through a group or population, it can become cultural transmission. This can then lead to development of, or change in, the behavior of groups, and there is some evidence to suggest that it can interact with natural selection as an evolutionary driver. Cultural transmission in combination with appropriate timescales and persistence through sufficient generations can select for specific behavioral traits within a population that may work as an additional factor in determining the evolutionary trajectory of a species or population.

The number of species, strategies, and transmission pathways through which cultural transmission works can make the generation of clear general theories difficult, but it highlights the level of ubiquity and importance of cultural transmission in the animal world. It is also an important area of current research, where many central questions remain open. Cultural transmission is an area which is currently and likely to remain a productive area of research for some time. Further evidence is needed to clarify some of the opposing theories pertaining to culture, and although cultural transmission can be much faster than genetic transmission, evidence of cultural transmission by definition requires monitoring of groups of animals over significant periods of time. Whether any, and how many animal species are capable of cultural transmission is a key step in furthering our understanding of the evolution of culture both animal culture as a whole and those of our own “special” human culture.

## Introduction

The word “culture” may evoke many different meanings depending on the audience. Such interpretations might refer to language, national identity, table manners, a style of cooking, art, or literature, for example. Consequently, a broad definition of the term is necessary to encompass everything that a diversity of writers describe as cultural. One such definition is that culture is a package of traditions, with traditions being behavior patterns common to more than one individual in a group which are transmitted between individuals by social learning (Hoppitt and Laland 2013). Another important feature of culture is that it is at least somewhat enduring, as opposed to the transmission of transient social information like “The building is on fire!” Culture may be transmitted “vertically” (between generations) or “horizontally” (within a generation). An example of

vertical transmission would be offspring observing and adopting their parents’ hunting techniques, whereas horizontal transmission could be teaching a friend to sew. Humans are, of course, highly dependent on culture. In many societies, this is emphasized by the enormous importance placed upon formal education for children and juveniles until a mandatory age, a recognition of the difficulties one can face in those societies without this baseline of cultural capital. Of course, our absorption of social information doesn’t end at leaving school. Friends, family, colleagues, media, and now the Internet all present a constant barrage of social information that we often cannot help but incorporate into how we perceive the world and act within it. But complex cultures have of course arisen also in societies that lack formal schooling or writing, whether in present times or more universally in earlier times.

Human culture has been recognized to be uniquely complex as a result of our capacity for “cumulative culture” (Dean et al. 2014), the ability to modify learned behaviors such that they become more complex and/or efficient, then be transmitted, and further improved by others until eventually a level of complexity is attained that could not have been achieved by a single individual. However, the capacity to pass traditions through multiple generations of social learners is not uniquely human. In fact, current evidence would suggest that it is ubiquitous in vertebrates and perhaps larger swathes of the animal kingdom.

## What Do Animal Cultures Look Like?

One of the earliest signs of culture in nonhuman animals (hereafter “animals”) was reported in Japanese macaques (*Macaca fuscata*). A group of monkeys on Koshima Island in Japan was regularly provisioned with sweet potatoes to supplement their natural diet, and researchers noticed that one individual, a juvenile female named Imo, had started washing her potatoes before eating them (Kawai 1965). This behavior involved dipping them in water with one hand and brushing away sand with the other, presumably to make them more palatable. In the subsequent 5 years,

this behavior spread to 15 of the 19 other individuals in her group. Consistent with social transmission, this behavior did not arise randomly in other individuals but rather followed lines of social affiliation. This crucial detail makes it likely that individuals copied others that they were close to rather than each independently discovered potato-washing behavior. A potentially problematic issue with this finding is that sweet potatoes are not a natural part of Japanese macaques' diet, and so it is not demonstrable from this study alone that they would develop cultural variants under natural conditions. However, it was enough to spark an interest in primate cultures, and several other naturally occurring traditions have now been attributed to Japanese macaques.

Later, McGrew and Tutin (1978) discovered that one community of chimpanzees (*Pan troglodytes*) was displaying a novel method of social grooming, in which the grooming partners clasp hands above their heads and groom with the other hand ("handclasp grooming"). This behavior was found to be common in one chimpanzee group in Tanzania yet absent in a second group whose territory lay only 50 km away. Given that the two groups belonged to the same subspecies and due to their geographic proximity were likely to have interbred in the recent past, the authors concluded that this behavioral difference was likely to be cultural rather than genetic in its origin. Determining the presence of culture by examining behavioral differences between communities and

whether they can be accounted for by ecological differences, such as availability of materials in the case of tool-use behaviors, is known as the "exclusion" method. This method was later applied on a much larger scale (Whiten et al. 1999) to collate observational data from seven long-term chimpanzee field sites. The researchers identified 39 behaviors which were common in some groups and absent in others (Fig. 1). These examples ranged from variation in foraging behaviors, such as nutcracking and termite fishing, to social behaviors such as handclasp grooming. The unique patterning of these traditions in each community means that one could identify the group to which an individual belongs simply by examining their behavioral repertoire, just as one might make inferences about a human's cultural identity based on their social customs. Similar approaches have since been applied to other members of the primate order, finding that orangutans (genus *Pongo*), gorillas (*Gorilla gorilla*), white-headed capuchins (*Cebus capucinus*), and spider monkeys (*Ateles geoffroyi*) all exhibit a great deal of behavioral diversity between groups that can be attributed to culture (though with fewer different traditions than chimpanzees).

However, there is some uncertainty over how conservative such counts of cultural variation are. For example, while the tools necessary for nutcracking may be available to multiple chimpanzee communities, it is not implausible that other foods are in sufficient abundance in certain

**Culture, Fig. 1** The putative cultures of wild chimpanzees reported in 1999. "Customary" acts are those typical in a community; "habitual" are less frequent but consistent

with social learning. Numbers identify behavior patterns in the catalogue attached to Whiten et al. (1999)

locations that the many years required to master nutcracking skill are not a worthwhile time investment. Genetic factors are also difficult to completely rule out. Langergraber and Vigilant (2011) identified a correlation between the cultural variation between chimpanzee communities and their genetics. However, with the geographic distances involved, one might predict this correlation regardless of whether behavioral variation is cultural or genetic in origin. Indeed, cultural variation may well drive such genetic differences. For example, in humans the cultural practice of cattle farming in certain human population appears to have led to the evolution of lactose tolerance in adults. Similarly, it has been found that cultural variation in foraging specialisms may have led communities of killer whales (*Orcinus orca*) to occupy different ecological niches for long enough that they are now demonstrating incipient speciation (Riesch et al. 2012). Indeed, if a particular cultural variant is adaptive and persists for long enough, then it will inevitably have an effect on genetic selection, which in turn may influence the development of future traditions. This feedback process is known as “gene-culture coevolution” and described by “dual inheritance theory” (Richerson and Boyd 1978).

That a significant portion of the behavioral repertoires of some nonhuman primate species is seemingly shaped by cultural inheritance presents a key point of commonality between these species and ourselves and seems likely to characterize our shared ancestry. However, this commonality extends far beyond the primate order, with compelling evidence for cultural transmission existing in a diverse range of species (Whiten 2017). For example, in meerkats (*Suricata suricatta*), researchers have found that neighboring groups differed in the time of day they would emerge from their burrows, despite frequent dispersal between groups (thus controlling for genetic differences) and a lack of any known environmental correlates (Thornton et al. 2010). Furthermore, some of the most compelling evidence for animal culture is found in the study of marine mammals. In 1980, a single humpback whale (*Megaptera novaeangliae*) was recorded as using a novel foraging method known as

“lobtail fishing.” Over three decades, researchers observed this behavior diffuse between closely associated individuals in a manner consistent with social learning (Allen et al. 2013). Further evidence of complex culture in humpback whales comes from studies of their vocal communication. Depending on where they live, humpbacks have acoustically distinct songs. However, following the migration of small numbers of individuals between two communities of whales, researchers found that their new group quickly and comprehensively changed their song to match that of the newcomers (Noad et al. 2000). This last example introduces culture in the domain of vocal behavior. As well as other marine mammals such as killer whales and sperm whales (*Physeter macrocephalus*), there is a large body of research demonstrating vocal dialects in a variety of bird and primate species. Though less often discussed than noncommunicative traditions, these are particularly interesting in that the primary function appears to lie in identifying and facilitating social relationships. This illustrates that social learning may allow individuals not only to optimize their use of their physical environment (e.g., learning to exploit a food resource) but also their social environment.

## Core Cultural Concepts

Although the typical measures by which culture in animals is quantified refer to patterns of behavior, it may be useful to think in more nuanced terms. In humans, cultural anthropologists have suggested that we should think of culture in terms of core concepts or “cultural cognitions” which may or may not elicit a range of related behaviors. A human example of this would be the emphasis placed on collectivism as opposed to individualism in Eastern cultures relative to Western ones and the ways in which these concepts manifest themselves in behaviors common to each culture. Discussing “concepts” with regard to animals is inherently problematic insofar as we cannot examine such states as we might through conversing with human participants. However, careful examination of animal behavior can allow us to

draw useful inferences. One example of how differences in “core cultural cognitions” might manifest in nonhuman animals comes from observation of stick-tool use behavior in two different Ugandan groups of chimpanzees. One of these communities (the “Kanyawara” group) frequently uses stick tools to access a variety of resources, such as termites. In another community (“Budongo”), stick-tool use is entirely absent. Knowing this, researchers (Gruber et al. 2009) introduced a novel resource, artificial honey-filled holes, to see how these two different cultures would respond. Just as with similarly located resources, the Kanyawara chimpanzees gathered stick tools to retrieve the honey, whereas the Budongo community used leaf sponges. Even when appropriate stick tools were provided next to the honey holes, a similar pattern prevailed. Kanyawara chimpanzees stripped the sticks of their leaves and used the sticks as usual, whereas Budongo chimpanzees ignored the stick and kept the leaves for sponging. This carrying over of a particular *type* of solution from pre-existing behaviors to a novel problem is perhaps suggestive that culture runs deeper than any individual behavior. Another interesting example of culture as a “mind-set” rather than a specific behavior comes from a longitudinal study of aggression in a troop of olive baboons (*Papio anubis*) (Sapolsky and Share 2004). During the 1980s, the most aggressive males of this group died of tuberculosis as a result of contact with human waste. As a result, the rate of aggressive encounters in the group was dramatically reduced, physiological measures of stress dropped in young males, and a higher than normal rate of intersex grooming and affiliation was recorded. Critically, this “pacific” culture persisted even after the remaining original males of the group had migrated elsewhere and was adopted by new males who joined the group from other communities.

### Why Is Culture Useful?

Individual or “asocial” learning is one means by which animals can adapt their behavioral repertoire to best suit their environment. It is potentially

costly, however requiring a significant amount of time or energy investment to explore different options. In more urgent scenarios, such as predator avoidance, experimenting with behaviors that have an unknown payoff may cost an individual their life. Copying the behavior of other individuals allows one to bypass this process to arrive at useful behaviors without paying these costs. Furthermore, when individuals do arrive at a novel and productive behavior, this allows for benefit not only to themselves but also for it to be passed on to kin and allies, enhancing their fitness. That cultural information may be passed through multiple generations to shape behavior in a similar manner to genetic inheritance has lead social learning to be referred to as “nature’s second inheritance system” (Whiten 2017). However, not all cultures emerge as a result of innovations to adapt to a physical environment. Innovations may also maximize the benefits of the social environment, such as facilitating social bonding (as in cultural variations in handclasp grooming behavior in chimpanzees) or identifying oneself as a member of a group (such as group-wide convergence in vocal dialects). There is much evidence that humans may give preferential treatment to those who share their language, appearance, and culture, but whether animals also demonstrate such “in-group” bias based on cultural practices is not yet known. However, in species with extended periods of parent-offspring-directed social learning or high within-group relatedness, culture may function as a useful cue for identifying kin. Some animals may even purposefully diverge from the behavior of out-group individuals in order to make the difference clear, as suggested by the fact that captive pygmy marmosets (*Cebuella pygmaea*) changed the acoustics of their vocalizations to diverge from a newly introduced neighboring group (Elowson and Snowdon 1994).

The importance of complementary experimental work, such as the honey-hole chimpanzee study described above, to check and verify field observations is illustrated by studies into the toolmaking practices of New Caledonian crows (*Corvus moneduloides*). Crows from different regions of New Caledonia are known to construct

different types of tools for foraging, despite similar apparent availability of tool materials and prey. It has therefore been suggested that this may be an example of cultural variation and even cumulative culture. However, it was later found that hand-raised crows would spontaneously manufacture and use similar tools (Kenward et al. 2005), suggesting that while social learning may well facilitate the learning of this behavior in the wild, it is not essential. This example highlights an important issue with studying culture in wild animals, which is that one is often having to make post hoc inferences about an existing distribution of behavior. One can collect data consistent with a behavior being either socially learned or developmentally fixed, but without direct observation of the propagation of a behavior (as with the cetacean examples above) or experimental intervention, it is difficult to draw firm conclusions and its cultural status. Experimental work in both captivity and the wild allows us to systematically determine a species' capacity for social learning, as well as how exactly a behavior progresses from being an idiosyncrasy to a full-fledged group-wide tradition. Questions over how culture is transmitted can be usefully split as to whether they concern social learning *processes* or social learning *biases*. Processes refer to how information is transmitted between two individuals, and biases refer to the factors that guide when and toward whom individuals choose to copy. We next summarize the literature on each of these topics. Readers are encouraged to consult the “► Cultural Transmission” and “► Social Learning” chapters within this collection for a more comprehensive treatment.

## Social Learning Processes

Social learning processes are differentiated in terms of what information is being utilized by social learners and how it is dealt with cognitively. For example, **local enhancement** is one such process, whereby individuals learn by focusing their attention on a location that others preferentially acted upon. If many conspecifics are feeding in an area, this suggests there is an abundance of

food there and it makes functional sense for the learner to focus in a similar way. **Stimulus enhancement** is very similar, except that attention is drawn to certain objects rather than locations.

Researchers have distinguished between two principal higher-level processes: **imitation** and **emulation**. Imitation refers to copying the bodily actions of an individual, for example, the technique with which they manipulate a tool to achieve a goal, such as using a saw to cut a piece of wood in half. Emulation, on the other hand, refers to learning the outcome of a behavior and finding one's own path to achieving it, for example, breaking a piece of wood over one's knee instead of using the saw that the individual observed had used. The key difference is copying the *result* rather than the *form* of an action. Depending on the task, a learner's pre-existing knowledge, and the range of options available, they may well end up using essentially the same method as the demonstrator even if learning was not imitative, making disambiguation difficult. Of the two processes, imitation is commonly considered to be the most sophisticated form of social learning, since it allows for high-fidelity transmission of complex behaviors and requires the demanding translation of visual (or vocal) patterns seen in another individual's actions into commands in one's own motor system, to bring about the correspondence between the two despite a quite different perspective.

Whether and/or which animals are capable of imitation has long been a contentious issue. Tomasello et al. (1987) found that although young chimpanzees faced with an out-of-reach reward did not precisely copy a sequence of tool-use behaviors used by a conspecific to retrieve it, they did learn something of the *function* of stick tools for reaching such objects, and this was later described as emulation. In another study (Whiten et al. 2005), a single chimpanzee in each of the two different groups was trained on alternative methods of using a stick tool to operate parts of a foraging device, which would release a food reward. These alternative techniques spread throughout the models' respective groups to become recognizably different traditions, and while some individuals did explore other

methods, they were found to eventually reconverge on the behavior most common to their group. That the groupmates of these demonstrators converged on their methods is suggestive of imitative learning. “Ghost” experiments in which the movements of the device were made without any chimpanzee responsible, so could be replicated only by emulation, failed to lead to success, reinforcing this conclusion.

Long-term care staff of captive apes frequently have a long list of anecdotes about their animals copying the behavior of their carers, such as brushing one’s teeth or scrubbing floors. These behaviors, which serve no purpose for the ape (but may have been reinforced by their carers, knowingly or not), are difficult to explain without imitative learning and were common in the diaries of researchers studying home-reared chimpanzees in particular. Indeed, the environment in which individuals are raised may be critical in shaping such tendencies. It has been found that home-reared or so-called “enculturated” chimpanzees (referring to their immersion in human culture) demonstrate a greater proclivity for imitation than chimpanzee-reared individuals (and equivalent to that of children) when tasked with copying the actions of a human demonstrator (Buttelmann et al. 2007). Some evidence for bodily imitation has also been found in species as diverse as marmosets (*Callithrix jacchus*), bottlenose dolphins (*Tursiops truncatus*), and pigeons (*Columba livia*).

A social transmission process that is thought to particularly characterize humans is **teaching**. Even preschool children have been found to engage in spontaneous teaching behavior by verbally instructing their peers on how to solve an experimental problem (Dean et al. 2012). Together with imitation, teaching has been proposed as a critical high-fidelity process of cultural transmission that allows for the unique complexity of human culture (Galef 1992). However, whether teaching can be considered uniquely human is highly dependent on how one defines the term. A popular “functional” definition of teaching in comparative studies is that it is a behavior in which an individual modifies their own behavior only in the presence of an observer, which both facilitates learning in the observer and

does not benefit the actor (Caro and Hauser 1992). Using this definition, researchers have identified a broad range of species for whom there is evidence for teaching. For example, meerkats bring home scorpions in which they first remove the sting, but later present scorpions decreasingly disabled, allowing pups to progressively discover the skills necessary to hunt this dangerous prey in a safe and structured way (Thornton and McAuliffe 2006). Evidence for teaching defined in this functional way has also been offered in bees, ants, birds, and callitrichid monkeys but seems strikingly absent in the great apes. It has been suggested that this lack of teaching in apes may be due to long periods of immaturity which allow juveniles instead to learn necessary skills through extended observational learning.

## Social Learning Biases

Culture benefits an individual only insofar as these benefits outweigh those of learning individually (asocially). If an individual copies every novel behavior it observes conspecifics performing, then they may end up copying maladaptive behaviors or replacing perfectly useful methods with less efficient ones. Consequently, in order to maximize the benefits of social learning, it has been proposed that species with an evolved propensity for social learning are likely to also have evolved a suite of biases that guide when and toward whom it should be deployed. Understanding these biases is crucial to improving our understanding of how culture emerges and propagates, as well as the contexts in which it is most useful. They can be usefully categorized into “who” and “when” biases.

“Who” or “model-based biases” direct individuals toward copying specific individuals (such as one’s mother) or categories of individuals (such as kin). Humans demonstrate a number of such biases, such as children directing their social learning toward older and more prestigious individuals. Some animals also appear to be selective in their preferential sources for social information. For example, in an experiment where the method of opening a puzzle box was introduced to

chimpanzee groups by trained models, it was found that naïve individuals preferentially directed their attention toward dominant knowledgeable demonstrators (Kendal et al. 2015). A tendency to copy dominant individuals, or “rank bias,” has been proposed as a key factor in chimpanzee social learning. It may explain why so few chimpanzee innovations are recorded as going on to become group-wide traditions, since many innovations come from subordinate individuals. Dominant individuals typically also enjoy the greatest amount of reproductive success in a group and so are perhaps likely to be good role models. If their success is a result of their behavioral preferences, then copying them might bestow those same benefits on the learner. In many cases, the characteristics that make an individual dominant, such as physical prowess or being the offspring of a dominant individual, cannot be directly copied. In this case, converging on their behavior must serve another purpose. One possibility is that behavioral similarities facilitate social bonding between individuals, in which case copying the behavior of dominant individuals may serve an additional function of improving one’s social standing. However, when researchers seeded groups with a method of opening a puzzle box by either alpha male or subordinate female chimpanzees (i.e., only one model was available, whether of high or low rank), it was found that observers were highly motivated to copy the behavior of subordinate models (Watson et al. 2017). It may be then that individuals are motivated to learn visibly productive foraging behaviors from whomsoever they observe demonstrating them since learning this can only be beneficial, whereas transmission of more “arbitrary” traditions does indeed flow primarily from dominant individual models.

A bias toward copying one’s own kin appears to be common. For example, brown capuchin monkeys (*Cebus apella*) do not copy individuals based on their relative rank but do demonstrate a bias toward copying related models (Dindo et al. 2011). The vocal production behavior of killer whales is also known to be largely transmitted within matrilineal lines (Yurk et al. 2002). The capacity for kin bias to shape cultures is neatly illustrated in

vervet monkeys (*Chlorocebus pygerythrus*). It has been found that, within the same group of monkeys, multiple distinct methods of cleaning food before consumption were present in the group and were differentiated along matrilineal lines. In some species, kin bias may only manifest during specific developmental windows. For example, observations of wild chimpanzees suggest that infants are significantly more likely to observe the nutcracking behavior of related individuals than juveniles or adults. There are many possible reasons for a kin bias in social learning. The simplest would be that if one is raised by a kin, they provide the most opportunities for social learning. Kin-specific traditions could also help related individuals identify one another, which may be useful for avoiding them when choosing a mate or banding together to form social alliances.

On the other hand, if one’s parents have had a particularly stressful life, this may indicate that they are not behaviorally well-suited to the current environment and therefore make poor role models. Experimentally elevated stress hormones in zebra finch (*Taeniopygia guttata*) nestlings caused them to switch from the developmentally typical strategy of copying their parents to exclusively copying unrelated adults (Farine et al. 2015). This finding emphasizes that social learning biases may vary greatly within a species according to an individual’s own life history. Dominant chimpanzees, for example, are less likely to use social information than subordinate individuals. Furthermore, young white-headed capuchins are more likely to be influenced by social information than older individuals, but both old and young monkeys are influenced by the relative payoffs of the behaviors they observe. These facts demonstrate that social learning biases vary not just between species, or between individuals, but also within individuals during their own lifetime. More often than not, culture is therefore likely to be the result of a tapestry of interacting biases.

Computer modeling of social learning behavior predicts that a very effective way of getting reliable social information is, instead of targeting specific individuals, to simply copy the behavior of the majority of one’s group. This tendency to be

disproportionately likely to copy the behavior of a majority (as opposed to the likelihood of copying the behavior if choosing a model at random) is known as “majority-biased transmission.” This is occasionally conflated with “conformity,” but a useful distinction is that while majority bias is something naïve individuals may do, conformist behavior requires the additional feature of relinquishing an existing behavior to converge on a majority preference. Both of these biases have been proposed as being crucial for stable, long-term culture, as without some process causing individuals to converge on a group “norm,” traditions may be eroded through copying errors and novel behaviors. Consequently, these biases have received considerable research attention.

The study of conformity behavior has its roots in social psychology. A seminal series of experiments carried out by Solomon Asch in the 1950s (Asch 1951) tasked small groups of people with judging which of three lines of varying lengths was the same length as the fourth line. Unbeknownst to the sole participant, every other individual in the group was a confederate of the experimenter tasked with unanimously giving the same incorrect answer. Even though this answer was obviously incorrect, around 30% of participants gave the same answer when it was their turn. However, they often did not do so when able to give their answer in private. This is suggestive of a powerful motivation in humans to conform to the normative behavior of those around us, an effect which has been replicated across cultures and age groups. Given that this behavior is so widespread in humans, there has naturally been an interest in whether animals behave similarly.

There is evidence for conformity in nine-spined stickleback fish (*Pungitius pungitius*), which, after learning the relative payoffs of two artificial feeders, relinquished their trained preference in favor of feeding at the same location as a group of individuals (Pike and Laland 2010). Further evidence for animal conformity comes from male vervet monkeys. After migrating to different groups, these monkeys have been found to conform to the food preferences of their new group, even though they had previously found that food to be unpalatable. Conformity has also

been identified in great tits (*Parus major*), which learned one of the two methods of operating a foraging box and then migrated to groups who used the alternative method. It was found that many of these individuals gave up their original behavior to adopt that of their new group (Aplin et al. 2015). However, a criticism of these studies, and a general difficulty with investigating conformist behavior, is that it is often challenging to differentiate the outcomes of so-called conformity from other social learning biases or even random-copying. Great methodological effort is required to disentangle these alternative explanations.

Despite the apparently wide taxonomic distribution of conformist behavior discussed above, evidence in chimpanzees is mixed. Observations of wild chimpanzees have recorded females who migrate between communities converging on the materials chosen for nutcracking used by their new group, despite no difference in availability of materials (Luncz and Boesch 2014). However, experimental studies have repeatedly failed to demonstrate such conformity. On the other hand, naïve chimpanzees preferentially copy a token-exchange behavior demonstrated once each by three individuals rather than a single individual demonstrating an alternative method three times (Haun et al. 2013), revealing a majority bias.

## Cumulative Culture

Although most researchers would now agree that culture is a widespread phenomenon across the animal kingdom, there is something strikingly unique about human culture in the way in which it continues to grow in scope and complexity over time, with each generation of learners modifying and adding to the body of knowledge that came before them. The complexity of these accumulated modifications has continued to ratchet up until most of the artifacts and processes we engage with on a daily basis could not have been invented by a single naïve person even if they spent a lifetime attempting to do so. It is this capacity to “stand on the shoulders of giants” that has allowed humans to thrive in almost every habitat on Earth, and it is known as “cumulative culture.” In this

capacity, humans are unquestionably preeminent. However, the jury is still out on whether this is a difference in quantity or kind.

Candidates for any degree of cumulative cultural evolution are rare in animals, and it may surprise some that perhaps the most compelling example to date comes from homing pigeons. Researchers found that groups of homing pigeons (*Columba livia domestica*) that had individuals replaced over time successively built on the efficiency of their homing route to the extent that the group would home more efficiently than solo individuals or groups with fixed membership (Sasaki and Biro 2017). Several candidates for cumulative culture have also been proposed in wild chimpanzees. Perhaps the most convincing of these is one community's method of termite fishing. Rather than fish horizontally at large mounds, as most chimpanzees do, this group uses a selection of stick tools to dig underground. This process involves selecting a particularly robust stick to penetrate the earth (often using a foot to provide extra force, just as one might with a spade) and several slimmer stems for insertion down the resulting tunnel, which must be stripped of leaves and pulled through their teeth to produce a "comb-like" end (Sanz et al. 2009). Though impressive, these examples still pale in comparison to the complexities of human cumulative culture, ranging from sophisticated tool kits to languages and religions.

Direct comparisons of 3–4-year-old children and chimpanzees have shed some light on this. One critical difference lies in our unique capacity for language, as children have been found to quickly engage in verbal teaching in complex tasks, allowing them to (a) inform others they have the solution, (b) impart this to them, and (c) correct any copying errors. Another potential roadblock for chimpanzees in particular appears to be behavioral inflexibility. There is some evidence that chimpanzees tend to get "stuck" on a method they have learned for solving a particular problem, thereby preventing them from "ratcheting up" the complexity of these methods in a cumulative fashion. This behavioral conservatism might also explain some absences of conformist behavior in chimpanzees described above.

However, there is some evidence that chimpanzees are motivated to relinquish an existing behavior when it becomes sufficiently inefficient and a more productive alternative is demonstrated in front of them. One thing to consider in such investigations is that although contemporary human culture changes at an unprecedented rate, our technological progress was in fact relatively static for millennia of the *Homo* genus' history. For instance, while stone-"flaking" technology dates back to between 2.6 and 3.3 million years ago, the first known cumulative development from stone flakes to more advanced "Acheulian" hand axes did not occur until around 1.8 million years ago, followed by relatively little progression for another million years or so, which corresponds to hundreds of thousands of generations. In light of these time scales, identifying instances of cumulative culture in animals is likely to be difficult – wild chimpanzees, for example, have been directly studied for only three to four generations, by comparison.

For a more in-depth review of cumulative culture, see the corresponding entry in this volume.

## Summary

Once thought to be a uniquely human trait, culture is now demonstrably widespread in the animal kingdom, incorporating a range of behavioral domains including foraging, communicative, and social behaviors. With a suite of biases to guide its adaptive use, social learning allows individuals to benefit from the hard-won knowledge of their conspecifics while paying relatively few of the costs. This capacity allows for rapid adaptation to changing environments or selective pressures that complements and has a reciprocal relationship with genetic inheritance, as the use of social learning is both shaped by genes (giving us the capacity for social learning in the first place) and may shape their further evolution. The study of culture and cultural transmission in animals is therefore critical not only in understanding this phenomenon but also for our understanding of the broader evolutionary processes that have shaped animal life. Complementary studies

of both captive and wild populations, using a combination of experimental and observational methods, are yielding an increasingly detailed understanding of cultural transmission in animals. Through comparisons with humans, this also informs us about our own evolutionary history with regard to what has made human culture unique and what common roots it developed from.

increasingly more complex artifacts and systems (Boyd and Richerson 1995). By contrast, to many authors cumulative culture appears rare, if not altogether absent in nonhuman animals (henceforth “animals”).

Several animal species may show minimal or marginal grades of accumulation that we review below, but whether the products of this accumulation are truly beyond the innovative capabilities of any single individual remains a source of contention (Tennie et al. 2009). While some flexible modification of a tool, a foraging strategy, or a social behavior does indeed show cumulative like capabilities, this is arguably only a foundational step in relation to true cumulative culture. Human culture is characterized by such advanced technology that no individual could innovate the vast majority of our artifacts without using prior, socially endowed knowledge or skills. Instead, we build on the contributions of multiple innovators across generations to continually improve the productivity and efficiency of our technology, something no other animal shows such clear evidence of. Cumulative culture is also manifested in a profusion of other distinctive human domains, such as language, religion, science, and the arts.

## The Extent and Limits of Cumulative Culture in Chimpanzees

A majority of the debates on the existence of cumulative culture focus on our closest relative, the chimpanzee (*Pan troglodytes*), both because along with the less-studied bonobos, they are the species with whom we shared our most recent common ancestry and because their cultures appear to encompass the largest and most diverse arrays of traditions among nonhuman animals (Whiten et al. 1999). Chimpanzees possess some of the “raw ingredients” for cumulative culture, notably social learning (Whiten 2005), defined as learning from others, and innovative capability (Nishida et al. 2009), the latter defined as “the discovery of novel information, the creation of new behavior patterns, or the performance of established behavioral patterns in a novel

## Introduction

The unique worldwide distribution and success of the human species compared to other primates are rooted in our capacity for cumulative culture, building onto and modifying socially inherited behaviors and technology to create

context” (Reader and Laland 2001, p. 788). However, long-term field studies of wild chimpanzees indicate that while innovation may be common, most innovations fail to spread through the rest of the population (Nishida et al. 2009). Although chimpanzees can potentially display relatively advanced social learning mechanisms and adaptive biases for using social information, they have been suggested to employ these under far more limited circumstances than humans, with less intrinsic motivation to engage in social learning (Herrmann et al. 2007). While there is evidence that chimpanzees possess a portfolio of different social learning mechanisms, the use of these is constrained by parameters such as the complexity and transparency of the task at hand: there are clear differences between the application of these learning processes in humans and chimpanzees, with humans having a greater tendency not only to use social information but to predominantly rely on high-fidelity mechanisms, such as imitation.

There is evidence that chimpanzees share some social learning strategies with humans, notably from whom to selectively copy and when to do so (Laland 2004), such as a preference to copy behaviors exhibited by a majority of conspecifics (Haun et al. 2012) and a proclivity to copy high-prestige individuals (Horner et al. 2010). However there are also important interspecies differences. For example, Marshall-Pescini and Whiten (2008) found that chimpanzees did not build on an existing tool-use technique to adopt a more complex method they saw others use to achieve greater rewards so long as their simpler, well-rehearsed solution produced some payoff. It was suggested that chimpanzees might rely on a copy-when-dissatisfied social learning strategy and so did not show cumulative learning in this study. However, recent studies have found contrary evidence that chimpanzees will relinquish a working solution (i.e., one that reliably produces reward) to adopt an alternative, higher payoff solution (van Leeuwen et al. 2013). Another explanation for Marshall-Pescini and Whiten’s findings is that chimpanzees are often conservative learners; that is, when chimpanzees have mastered a sufficiently rewarding behavior, they lack the behavioral

flexibility to modify that solution, with obvious consequences for the cumulative capabilities of the species.

All this being said, it is plausible that some behavior exhibited by wild chimpanzees is the result of a limited cumulative process. Boesch (2003) argues that nut cracking using an anvil stabilized by supplementary stones is an elaboration on an ancestral hammering method. Similarly, Sanz et al. (2009) argue that simple, unmodified tools were likely the precursors of more complex fishing tools with design features such as brush tips made by pulling stems through their teeth. Complex tool kits are also employed by wild chimpanzees involving the use of several, multifunctional tools in sequential order, indicative of some form of accumulation (Boesch et al. 2009; Sanz et al. 2010). Boesch (2012) offers further candidate examples of cumulative culture in wild chimpanzees. That chimpanzees have the relevant capabilities for such limited cumulative change is supported by recent experiments with captive chimpanzees which have found some evidence of cumulative build up in solution complexity (Davis et al. 2016; Vale et al. 2017). However, there is of course a lack of direct historical evidence that modern wild chimpanzees’ forebears used any less elaborate tool-based solutions than those seen today, and thus the argument of technological accumulation remains speculative in this respect (Dean et al. 2013).

### Cumulative Culture: Other Species

While chimpanzees (as well as humans) are by far the most well-studied species with regard to cultural capabilities and particularly cumulative culture, studies of other animals have recently provided evidence of such cumulative capabilities. For example, on a touch screen task, baboons improved the efficiency of their solutions to a pattern reproduction task along a chain of social learning episodes (Claidiere et al. 2014). Initially, 15 baboons were trained to memorize and recall the randomized location of four red squares in a grid of 20, where the other 16 squares were white. An iterative chain system was then implemented

whereby the behavior of the current participant then became the target behavior for the next baboon (instead of the presentation of randomized squares). Through generations, a systematic, cumulative pattern of behavior emerged, resulting in improved task performance. These results echo those in earlier studies that showed similar effects in human artificial language learning transmission experiments. In this case, for both human language learners and the baboons, the cumulative changes are in efficiency rather than rising complexity, for the material products actually become simpler and hence easier to remember.

Some avian species have also provided evidence of accumulation in behavior. New Caledonian crows display relatively complex tool-based foraging techniques, the distributions of which are consistent with the complex versions having arisen from modification on the simpler form (Hunt and Gray 2003). However, a role for social learning in the acquisition of these techniques remains to be clearly established. Most recently, Sasaki and Biro (2017) offered evidence from a quite different context: pigeon homing. These authors showed that pigeons would adopt more efficient homing routes across “cultural generations” generated by successively removing experienced birds from groups and replacing them with naïve birds, with evidence that performance was improved via social learning from prior such “generations” of pigeons. The context for this effect is that homing pigeons are known to devise homing routes both individually, and as part of a collective. While novice birds are guided by more experienced “leaders” within the collective, they can also contribute route innovations. To test if homing pigeons could build on their homing behaviors to iteratively improve their routes via social information, Sasaki and Biro repeatedly paired experienced and naïve birds in homing dyads to complete a navigational task. Each pair was given 12 trials to establish their route. In succeeding generations, the novice bird from the previous generation graduated to being an experienced leader and was paired with a new novice individual, and so on for five generations, giving a total of 60 trials across all the dyads. When performance of these changing dyads was

compared to controls on the same navigational task, Sasaki and Biro found that the last two dyad pairs outperformed individuals who had performed the task 60 times each, as well as pigeons who had been in consistent dyad pairs across the 60 trials (i.e., had the same partner across all 60 trials). Thus, here we see evidence of iterative improvement of a solution through social learning, a hallmark of cumulative culture. Of course, we cannot say that the best route is necessarily outside of the discoverability zone of all individuals, only that social learning across generations led to greater behavioral change and a subsequent convergence on the optimal route.

Other suggested examples of cumulative culture concern the songs of both birds (Lipkind and Tchernichovski 2011) and whales (Garland et al. 2017), which have been documented to change over time and, in that sense, evolve. The elaborate complexities of some songs suggest they may have arisen by cumulative culture; yet, as in many candidate examples other than experimentally controlled cases like those outlined above, we are handicapped by not having the historical records to confirm this.

In summary, the evidence for cumulative culture is very limited in nonhuman animals, and moreover a huge gulf lies between candidate behaviors for accumulation in animals and the technological and other complexities achieved in human culture.

## What Factors Are Limiting the Evolution of Cumulative Culture in Animals?

The core theoretical reasons for a lack of cumulative culture are commonly attributed to limited abilities to faithfully copy a behavior via observation from another individual, that is, to faithfully replicate the behavioral sequence inherent to a skill or artifact. As behaviors become more complex, an inability to copy their inherent action structure leads to errors in the replication process, and a likely failure to produce a functional result. Hence, even if complex innovations are invented in a species, without an ability to replicate them, they will remain unique to the innovators and fail

to spread to conspecifics. By contrast, humans readily learn from others' innovations through mechanisms such as imitation and teaching.

Low-fidelity social learning mechanisms may be one reason why nonhumans are limited in their cultural capabilities, but they are by no means the whole story. Other likely explanations are centered on the heuristics, or decision rules, governing when to change known solutions to a problem and adopt (or attempt to adopt) a potentially more optimal solution. This may be considered an "explore versus exploit" decision. Decisions which involve the use of social information are often referred to as social learning strategies (Laland 2004). For example, humans may employ a strategy such as "copy when better": when we observe a behavior which is superior to our own in terms of payoff or efficiency, we may choose to copy based on that comparison. This is a powerful driver of increasing behavioral complexity and leads to more productive outcomes inherent to cumulative culture (Mesoudi 2011). In contrast, nonhumans may rely on less cognitively demanding strategies, such as "copy when dissatisfied": instead of taking optimality of behavioral variants into consideration, an animal may take into consideration only whether their own current behavior is producing some satisfactory outcome. Regardless if there exists a far more productive alternative solution to a problem, the individual will persist with their own behavior. This would lead to a stall in behavioral accumulation because once a satisfactory solution is found, the individual will cease to explore the problem space, limiting the opportunities to build on behavior and enter into the realms of cumulative culture.

A further constraint on culture is the behavioral flexibility of a species, individuals' disposition or ability to relinquish or modify an existing solution. While typically a lack of behavioral change is ascribed to some suboptimal use of information, such as a failure to adopt another variant due to low-fidelity transmission or a stasis-inducing learning strategy, it is quite likely that many species may be behaviorally inflexible due to limited cognitive resources. With finite resources, an individual may struggle to inhibit the use of an old

solution while simultaneously holding in mind the new solution, and then switching to this new solution.

## The Slow Emergence of Cumulative Culture in the Human Animal

The high-fidelity social transmission processes of humans, along with the social learning strategies we employ, are thought to be responsible for allowing us to continually build upon the innovations of previous generations. When and how our ancestors acquired the ability to "ratchet" cultural complexity over time is still unclear. Although Oldowan technology exceeded the capabilities of extant wild great apes (Whiten et al. 2009), it was not for another million years that we begin to see significant advances, with the advent of Acheulean technology. It was not until between 160,000 and 40,000 years ago that we really see an unprecedented acceleration in cumulative culture. It is likely that before this time, our ancestors, although perhaps capable of halting cultural ratcheting, had reached some technological ceiling in the Stone Age. What, then, changed? Although there are several hypotheses, it has been suggested that technology eventually overtook that of other species due to changes in hominin social organization and demographics (Henrich 2004). Whether the changes in hominin cultural capabilities were driven by socio-cognitive advancements which led to changing demographics or vice versa is hard to disentangle. Either way, the increasing sociality of hominins may have led to the advancement of already existing social learning skills such that, over time, stable and complex cumulative culture became possible, as evidenced by later Acheulean technology. This is consistent with models which suggest that cultural complexity is achieved when learners have access to large social networks of individuals (Enquist et al. 2010) and is supported by experiments examining the effects of the number of available models on skill advancement and cumulative achievements (Derex et al. 2013). With increasingly sophisticated social organization, our ancestors would have been in a

position to donate technology (such that a learner could forego steps within the ratchet) and allow for specialization and division of labor within groups. Increased network size also means greater opportunities to learn from innovators via increasing the pool of innovators available, as well as sharing and collaborating in knowledge generation and technology (Tomasello et al. 2012).

Our ability to maintain, propagate, and continually build on complex knowledge, skills, and technology has afforded our species a highly advanced “second inheritance system” (Whiten 2005). Cumulative culture has allowed us to far exceed the general intelligence of any other known species, to cultivate resources in an unprecedented way, and to modify our environment to fit our needs and convenience.

## Curiosity

Wojciech Pisula

Institute of Psychology, Polish Academy of Sciences, Warsaw, Poland

*Oxford English Dictionary*

1. A strong desire to know or learn something
2. An unusual or interesting object or fact

*Cambridge Dictionary*

1. An eager wish to know or learn about something *to arouse/excite/satisfy someone's curiosity*

*American Dictionary*

1. An eager desire to know or learn about something

There is not a single universally accepted definition of curiosity, but research on this phenomenon is dominated by three main traditions. The first and oldest builds on the drives theory (exploratory and boredom drives). The second is linked to the ideas of D. O. Hebb, which draw on the hypothetical state of optimal arousal. The latest approach emphasizes the “informative” aspect of exploration. The most widely accepted definition is that of “epistemic curiosity,” which Berlyne described as a drive aimed “not only at obtaining access to information-bearing stimulation, capable of dispelling uncertainties of the moment, but also at acquiring knowledge” (Berlyne 1966, p. 31). Since the first two traditions specifically seek to explain exploratory behavior in animals, they will not be discussed in this paper. Regardless of the specific theoretical claims, the key element in curiosity-stimulating mechanisms is the novelty of the stimulus.

There are two aspects to the rewarding properties of novelty. The first is linked to the fundamental mechanism of sensory reinforcement, first observed in 1950s and subsequently incorporated into a theoretical system by D. O. Hebb (1955) and G. B. Kish (1955). Sensory reinforcement is a primitive mechanism in animal behavior and it is largely independent of novelty. For instance, rats may learn to push a lever in Skinner boxes by being rewarded with a weak light stimulus, but that effect does not disappear with progress in learning. When complete contingency between the behavior under study and the exposure to the stimulus is established, the reinforcement mechanism does not fade. Animals still display instrumental reactions even though there is no novelty and no element of uncertainty in a given situation. This phase of behavior can be described as stimulus-seeking behavior, which is basically driven by the second motivational component, namely, stimulation-seeking. At the heart of the controversy surrounding the rewarding properties of novelty lies the concept of novelty itself. Interpretative problems arise when analyzing animal behavior when faced with complete novelty. What needs to be

determined in this context is whether complete novelty is merely a complete change in the configuration of environmental elements, or whether it must also involve a change in the intensity of stimulation.

Regardless of the neural basis for various motivational processes, which may differ between organisms at various stages of evolutionary development, the rewarding, pleasure-inducing character of stimulus novelty is undoubtedly the most important aspect. The willingness to detect, recognize, and seek novelty must be regarded as a fundamental motivational process regulating human and animal behavior alike. Exploratory behavior, which is aimed at investigating the environment, seems to be the natural foundation for human curiosity about the world. Undoubtedly, exploration plays an important part in human and big-brained animals' behavior. Whether fairly simple or highly complex, exploratory behaviors form part of the behavioral repertoire.

D. Berlyne (1962) was the first researcher to study curiosity in a systematic manner. Although Berlyne himself did not make use of the integrative levels theory as a theoretical tool, his concept of "epistemic curiosity" may undoubtedly be regarded as the most advanced form of exploratory behavior (Pisula 1998). Berlyne saw curiosity as a product of the same processes that had shaped the evolution of human and animal exploratory behavior. He coined the term "epistemic behavior" to denote activity triggered by cognitive curiosity. Epistemic behavior comprises three categories: epistemic observation, which includes experimental and other observation-based scientific techniques; consultation, which involves asking other people questions or consulting reference books, databases, networks, and other sources of information; and directed thinking. Epistemic observation seems to be a direct product of perceptual exploration and manipulation. The purpose of this activity is to gather nonsymbolic information, which means observable indices, registered directly by our senses or with the help of scientific equipment. Observation is undoubtedly driven by symbolic processes, but in the case of

epistemic observation, the fundamental aspect is the focus on phenomena directly observable through the senses or scientific tools.

Consultation is an important advantage in the process of information-seeking in humans, when compared to other animals. Asking questions, searching for answers in online documents, databases, books, libraries, and other modern sources of information – all this helps construct the image of the modern human being as endowed with an insatiable appetite for information.

Directed thinking is a particularly intriguing and complex area. On the one hand, prolonged fixation of thought processes on a single object may be a symptom of pathology: Berlyne noted certain similarities between directed thinking and autistic thinking. However, in the first case, an individual is able to resist persistently returning to the same train of thought, to view a given issue from various perspectives, and to produce new content in a creative manner. Human curiosity is a recurrent motif in cognitive psychology and the psychology of creativity. D. Berlyne was also the first to list curiosity-arousing factors which he labeled "collative variables." These variables include: novelty, complexity, and surprise. Berlyne treated these variables as quantifiable, although he admitted that measurement could be problematic. This means that a given stimulus could be described in terms of the degree of novelty or complexity.

This part of Berlyne's analysis has come to be regarded as a lasting contribution to the body of knowledge about cognitive curiosity. Some of the ideas related to motivational processes proposed by Berlyne are debatable, but the validity of his conceptual system describing the properties of stimulation that triggers curiosity has never been challenged.

Three decades later, George Loewenstein (1994) systemized scientific knowledge about epistemic curiosity by making a clear distinction between information-seeking behaviors related to factors occurring in environmental settings, on the one hand, and intrinsic factors evoking curiosity, on the other. Many people (managers, patients wishing to find out about their prognosis and treatment options, journalists, etc.) constantly

seek information. Some of them do it as part of their professional duties, but one could hardly describe their curiosity as intrinsically motivated. Their actions are shaped by their roles, circumstances, or professions. G. Loewenstein noted another vital aspect of human curiosity: in order to become curious, the individual must realize that he/she has less information about a given subject than is generally available. The urge to close that information gap is the key factor driving curiosity. Loewenstein's reasoning is linked to *Gestalt* psychology and modern cognitive psychology.

In a more recent work, Loewenstein slightly modified his terminology. Although the term "epistemic curiosity" is widely accepted by researchers not directly involved in this field of research, experts in the field criticize it as too general and of little scientific use. The term that has gained popularity instead is "interest." In his elaboration of Loewenstein's concepts, P. J. Silvia (2008) considered the advances in modern psychology of emotions and stress. Referring to the functional analysis of emotions, he defined the function of "interest" as motivation for learning and exploration. Novelty, complexity, unexpectedness of stimulation can evoke curiosity, in accordance with Berlyne's classic theory. The prerequisite, however, is comprehensibility. Humans try to understand a novel situation. If an individual's assessment of such a situation results in a positive conclusion about the individual's ability to cope with the demands, then curiosity is aroused, which leads to learning, exploration or, as suggested by Loewenstein, to closing the information gap. However, if the conclusion from this initial assessment is that the demands of the situation are excessive (e.g., the material at hand is too difficult for the subject to learn), what follows is withdrawal and stress.

Research confirms this hypothesis. J. A. Litman, T. L. Huthins, and R. K. Russon (2005) conducted an experiment in which they manipulated the information gap from the "I know" status through "Tip of the tongue" to "Don't know." It showed that curiosity was mostly triggered by the "tip of the tongue"

situations. They corresponded to sensations described by the participants as "sense of knowing." The participants also typically defined curiosity as significant information deprivation and adjusted the intensity of exploration accordingly. The "I know" category did not arouse curiosity or exploration. The "Don't know" situations did not trigger a much curiosity defined as deprivation of knowledge about a given subject, but evoked positive attitudes characterized as "interest."

T. G. Reio Jr. J. Petrosko, A. K. Wiswell, and J. Thongsukmag (2006) verified the validity of epistemic curiosity using psychometric data. In a comprehensive study conducted on a few hundred students, they collected results from several scales measuring various forms of curiosity. The Confirmatory Factor Analysis confirmed that human adults demonstrate two main forms of curiosity: cognitive curiosity and sensory curiosity. The latter may be clearly divided into two subcategories: physical thrill seeking and social thrill seeking. Those subcategories are the main components of what M. Zuckerman called "sensation seeking" (Zuckerman 2003). Cognitive curiosity is a typically human mechanism involving hunger for information whereby the key element is the information content of stimulation. In the case of sensory curiosity, the human brain is saturated with pleasant sensory stimulation associated with physical or social activity.

Similar results were obtained by J. A. Litman and P. J. Silvia (2006), who also conducted a study on several hundred participants, using a series of tests measuring various forms of curiosity. They obtained a similar main effect of a factor which they called Epistemic Curiosity, after Berlyne (1962), and a second factor called Curiosity Deprivation. Despite the differences in the theoretical approaches adopted by the aforementioned authors, the structure of the dimensions they proposed involves some stable model of information-oriented curiosity (epistemic or cognitive) and sensory, or stimulation-oriented curiosity (sensory/deprivation). There are solid grounds for believing that the perceptual exploration observed in higher animals is a prerequisite for the development of

sensory curiosity, which in turn is the basis for the development of the typically human curiosity, which we may call “information curiosity” or “information hunger.”

There have been many publications about the role of curiosity in animal and human behavior, which clearly suggests that its importance must not be underestimated. Satisfying one’s curiosity is a powerful reward in itself. For this reason, it would seem that our knowledge about sensory reinforcement, curiosity, and exploration may provide sufficient basis for developing a friendly and stimulating educational environment. As recently pointed out by Kidd and Hayden (2015), however, there are several basic questions that still require more definite answers. The four crucial ones are:

- In what ways does curiosity resemble other basic drives? In what ways is it different from those drives? To what extent is curiosity fundamentally different from drives like hunger and thirst?
- What is the most useful taxonomy of curiosity? How well does Berlyne’s categorization hold up? Which factors are common to the various distinct forms of curiosity?
- How is curiosity controlled? Which factors govern curiosity, and how does the brain integrate these factors into decision-making to produce decisions? To what extent is curiosity context-dependent?
- To what extent does curiosity in nematodes overlap (if at all) with curiosity in children? How useful is it to think of curiosity as being a single construct across a broad range of taxa?

Curiosity is therefore an intriguing aspect of regulating human and animal behavior which merits further research.

## Cylinder Task

Juan F. Duque<sup>1</sup> and Jeffrey R. Stevens<sup>2</sup>

<sup>1</sup>Department of Psychology, University of Nebraska-Lincoln, Lincoln, NE, USA

<sup>2</sup>Department of Psychology, Center for Brain, Biology and Behavior, University of Nebraska-Lincoln, Lincoln, NE, USA

### Synonyms

[Detour-reaching task](#); [Detour task](#)

### Definition

A task that measures inhibitory control – the ability to inhibit inappropriate or disadvantageous responses – using a reward placed within a transparent cylinder. Subjects must inhibit moving directly toward visible reward and instead reach through one of the cylinder openings at either end.

### Introduction

A lioness spots a gazelle several meters away on a hill, but a line of tall savannah grass separates her from her prey. She can proceed directly toward the gazelle, but crashing through the grass would alert the prey to her presence. Alternatively, she could inhibit the impulse to run straight toward the prey and detour around the tall grass to a better location from which to launch her attack. Similarly, a subordinate chimpanzee may inhibit its desire to mate or forage when in view of a dominant conspecific but seek those opportunities when out-of-view behind a barrier. Animals face many problems that require them to inhibit an action in lieu of a different, more goal-consistent behavioral strategy.

Inhibitory control is the ability to inhibit a powerful, almost automatic (prepotent) response. Since prepotent responses often run counter to one's goals, inhibitory control is a core feature of

executive functioning – the top-down cognitive control processes that allow individuals to remain on track and achieve desired goals. In the case of the lioness, she must inhibit the prepotent desire to move directly toward visible prey.

Researchers have used many tasks to measure inhibitory control (Table 1). Detour tasks require subjects to detour around an obstacle or barrier to reach a desired location. The cylinder task is a specific form of detour task in which subjects must retrieve a reward, typically a food item, from within an opaque or transparent cylinder. This task, along with other detour tasks, requires subjects to first inhibit the prepotent motor response to move directly toward the visible reward. Instead, they must detour around the barrier walls to obtain the reward through an available opening.

Other tasks require less motor action by focusing on choice or the withholding of responses. In reverse contingency and A-not-B tasks, subjects attempt to obtain a reward by choosing between a set of limited choices, with the prepotent choice not providing the reward. Similarly, Go/no-go tasks train subjects to respond to a frequently presented stimulus, but this prepotent responding must be inhibited in certain situations. In delay of gratification tasks, individuals must inhibit taking a reward that is available immediately or after a short delay to obtain a more desirable reward available after a longer delay.

### Cylinder Task Procedure

The basic procedure of the cylinder task involves three phases:

- **Habituation phase:** Subjects habituate to the testing environments. This often involves exposure to elements of the task that subjects have never, or rarely, encountered, such as exposure to human experimenters, tracking hand movements, and the presence of opaque cylinders.
- **Training phase:** An experimenter baits an opaque cylinder by placing a desired reward in the center (Fig. 1a). To correctly respond,

subjects must detour around the opaque cylinder and reach through one of the openings to obtain the reward. Touching any part of the opaque wall first counts as an incorrect response. To proceed to the next phase, subjects often must reach a certain criterion level of success, typically 80% correct responses in consecutive trials.

- **Testing phase:** This phase is the same as the training phase, except with a transparent cylinder (Fig. 1b). Subjects must inhibit their

prepotent response to reach directly for the desired reward, hitting the transparent wall. Instead, they must continue around to the ends of the cylinder to acquire the reward. Researchers often measure performance as the proportion of correct responses or the number of test trials required until the first correct response.

**Cognitive Capacities for Inhibitory Control**

Correctly avoiding the barrier and detouring through one of the openings requires several cognitive capacities. In the training phase, the subject must maintain a memory of the object after it is hidden inside the opaque cylinder (object permanence). In the testing phase, the subject must understand the nature of physical barriers. In particular, they must understand the solidity principle in which one solid object cannot pass through another solid object. This is particularly relevant to transparent barriers where a subject’s visual and tactile cues conflict. Lastly, the subject must combine knowledge and solve the problem at hand to achieve the goal of obtaining the reward. Subjects can see the reward through the transparent barrier, but they cannot directly access the food; therefore, they must move around the barrier to reach the reward. To succeed in this task, subjects must understand the physical state of the world

**Cylinder Task, Table 1** Inhibitory control tasks

| <i>Detour tasks</i>           | <i>Example reference</i>    |

| Accumulation                  | Beran et al. (1999)         |
| Exchange                      | Ramseyer et al. (2006)      |

**Cylinder Task, Fig. 1** The cylinder apparatus. The training phase involves obtaining a reward from within an opaque cylinder (a). After reaching criterion, the testing phase involves the same procedure, except with a transparent cylinder (b). Subjects must inhibit the prepotent response to move directly forward and instead detour through one of the cylinder openings (Used with permission from MacLean et al. 2013)

(object permanence and solidity principle) and exhibit an appropriate behavioral response (detour-reaching).

Behavioral Results

The simplicity of the cylinder task makes it easily amenable to comparative studies. Indeed, researchers have tested several dozen species, ranging from pigeons to primates. Overall, great apes, capuchin monkeys, rhesus macaques, canids, and corvids perform the best with greater than 70% correct responses (Fig. 2). Interestingly,

some corvids match or even surpass the performance of great apes.

Researchers have examined several evolutionary factors that may account for these species differences in performance. Phylogenetic comparative methods indicate that absolute brain volume predicts species differences in performance, along with relative brain volume and dietary breadth. However, species differences in performance may also result from how the animals engage in the task. Factors such as a subject’s motivation, prior experience with opaque/transparent barriers, amount of habituation and training trials prior to testing, and the degree of experimenter

Cylinder Task, Fig. 2 Species performance in cylinder task. MacLean et al. (2014) and Kabadayi et al. (2016) tested a combined 36 species of birds and mammals in the

cylinder task. They report each species’ mean percentage of correct trials during the testing phase

involvement during the task can influence performance. Therefore, without further investigation into the various contextual factors that impact performance, species differences should be interpreted with care.

The cylinder task is one of a suite of inhibitory control tasks. To assess whether inhibitory control is a unitary construct, researchers have tested the same subjects in multiple inhibitory control tasks. In general, within-individual performance across inhibitory control tasks, e.g., A-not-B and the cylinder task, does not correlate. These findings suggest that inhibitory control is multifaceted and that different inhibitory control tasks vary in the precise mechanisms activated.

## Conclusion

Inhibitory control is a critical component of executive functioning, ensuring that individuals maintain appropriate, goal-directed behavior. Detour tasks, such as the cylinder task, test an individual's ability to inhibit a prepotent desire to move directly toward a visible reward. Species vary in their propensity to correctly solve the detour task, and there may be evolutionary reasons for the species differences. Yet, we currently do not have a clear understanding of the contextual factors influencing performance on the detour task. Such data would be useful in elucidating the proximate mechanisms subjects use during task performance and could clarify why results across multiple inhibitory control tasks do not always correlate.

### Synonyms

[Daughter-guarding hypothesis](#); [Parent-offspring conflict](#)

### Definition

A hypothesis designed to describe parental control of sexual behavior and mate choices of daughters.

### Introduction

Human mating decisions are not made in a social vacuum; rather, members of the local community and external surroundings, especially close kin and coalitional allies, affect them. Parents can be particularly powerful influencers of their children's mating decisions because of their unique position in their children's lives. Parents are typically proximately close and may provide

substantial resources to children that are required to pursue mating choices, giving parents special leverage over children compared to others (Apostolou 2007, 2010; Perilloux et al. 2008). In anthropological investigations of marriage types across hunter-gatherer societies, parent-arranged marriages are the most common, occurring in 69% of societies. Close kin arranged marriages (marriages arranged by family members other than the parents) were the next most common, occurring in 18% of societies (Apostolou 2007). These two types of marriage were the most common marriage types in all geographical areas surveyed.

Parents are particularly motivated to influence their offspring's mate choice because of the closely linked reproductive consequences. Parents share a genetic relatedness coefficient of 0.50 with their offspring, meaning that decisions by offspring greatly impact parental fitness, including in the form of grandchildren with whom they share a genetic relatedness coefficient of 0.25. The parents, particularly the mother/maternal grandmother, will be certain that the grandchild is related to them. Investing in their daughter and daughter's children may be more profitable than investing in a son and son's children as there is more certainty of genetic relatedness in the former than in the latter (Apostolou and Papageorgi 2014; Perilloux et al. 2008; Trivers 1974).

Additionally, successful mating decisions may lead to myriad benefits including high-quality genes, resources, protection from threats, social alliances, social status enhancement, and psychological support required for survival and reproduction. These benefits give parents motivation to intervene in their children's mating behaviors (Apostolou and Papageorgi 2014). Anthropological studies indicate that fathers more than mothers attempt to control their children's mating choices, and this control is more focused on daughters (Apostolou 2012). Fathers may have more to gain than mothers from marrying their daughters to other men, including social status, powerful allies, and riches obtained from suitors and their families (Apostolou 2012; Perilloux et al. 2008). This can affect father's successes if they are able

to obtain new wealth or become more reproductively valuable as a consequence.

While parents guide their offspring to make particular mating choices, conflict arises as the two parties (parents and offspring) often do not agree. Conflict between parents and offspring about mate choice occur in many domains, including valuations of a prospective mate's traits. Parents and children are genetically related, but not genetically identical; their genetic interests overlap but also diverge (Trivers 1974). The desires of children compared to parents differ in terms of which traits are viewed as most valuable in a mate. Adult children more than their parents prefer characteristics signaling genetic quality (i.e., physical attractiveness and intelligence), while parents more than children value characteristics signaling future investment in grandchildren and in-group cooperation (i.e., similar religious belief, similar social status, or ethnic background) (Apostolou 2010; Fugère et al. 2017, Perilloux et al. 2011). These findings are robust across cultures. To improve their own fitness, offspring seek mates of high genetic quality; while to improve parent's fitness, parents are interested in in-group cooperation and investment in future children (Dubbs et al. 2013; Fugère et al. 2017).

Across cultures, parents behave differently toward sons and daughters in their attempts to influence mate choices and sexual behaviors. The consistent trend is that parents perform more behaviors to dissuade, manipulate, reduce, or thwart sexual behaviors of daughters compared to sons (Perilloux et al. 2008). The research conducted by Perilloux et al. (2008) led to the Daughter-Guarding Hypothesis. This hypothesis states that humans have adaptations that motivate protecting their daughter's sexual reputation, preserve their daughter's mate value, and prevent their daughters from being sexually exploited (Perilloux et al. 2008). Perilloux et al. (2008) administered questionnaires to parents asking how likely they would be to allow their children to engage in various behaviors. These questions ranged from clothing choice, mate choice, driving behaviors, and curfews. The results indicated that parents were much stricter with their daughters than with their sons in the majority of

circumstances. This survey also included four questions focused on parental attitudes related to guarding, asking about parent approval of their child's sexual activity. Once again, daughters were held to stricter standards and caused greater parental upset than sons performing the same acts (Perilloux et al. 2008). Children of these parents also completed a survey and daughters reported significantly less parental approval of each of the four acts compared to sons.

Manipulation is a common tactic that parents use to influence the mate choice of their offspring in Western, postindustrial societies, because in the modern environment, resources are more equally distributed among offspring and fewer arranged marriages occur in Western societies (Apostolou and Papageorgi 2014). Manipulation is used more often on daughters than on sons (Apostolou and Papageorgi 2014). In addition, mothers more than fathers report use of more manipulation tactics on their children to influence mate choice (Apostolou and Papageorgi 2014). Children also use manipulation tactics to persuade their parents to accept their mate choices or to persuade them to change their assessment of particular mating relationships. Daughters use manipulation tactics against parents more than do sons (Apostolou and Papageorgi 2014). Daughters' manipulation of parents may be designed to secure a mate that possesses more characteristics signaling high genetic quality rather than future-oriented commitment and investment.

Daughter guarding may occur to protect the fitness interests of the daughter as well as parental fitness interests. When comparing sons and daughters, parents are more likely to guard daughters than sons because of asymmetries between the sexes (Perilloux et al. 2008). Sexual asymmetries in reproductive biology produce sex differences in costs from recurrent adaptive problems such as rape, sexual victimization in other forms, and unwanted pregnancy. Women incur more costs from each of the aforementioned adaptive problems (unwanted pregnancy, violence and pain, or tarnished reputation) leading to more protection from parents (Trivers 1974). An early example of daughter guarding was identified by Flinn (1988), who documented that

fathers living in a Trinidadian village required their daughters more than their sons to take chaperones with them wherever they went, thus restricting their daughter's movements more than their son's. These fathers also threatened other men who came to visit their daughters (Flinn 1988).

## Conclusion

Daughter guarding is executed by parents to protect their daughters from sexual exploitation and from making mating decisions that parents perceive as mistakes. Protection manifests in many forms, including vigilance, strictness, forbiddance, curfews, chaperones, and dress codes. Daughters are subjected to greater parental guarding than sons as the certainty of relatedness of parents to resulting offspring by daughters is greater than to offspring by sons, in addition to the greater harm that daughters (and therefore parents) face from sexual exploitation of women by men.

## David Attenborough

Karthikeyan Pethusamy<sup>1</sup>, Sai Krishna Bhamidipati<sup>2</sup> and Asutosh Tiwary<sup>3</sup>

<sup>1</sup>Department of Biochemistry, All India Institute of Medical Sciences (AIIMS), New Delhi, India

<sup>2</sup>National Institute of Immunology, New Delhi, India

<sup>3</sup>Acharya Narendra Dev College, New Delhi, India

David Frederick Attenborough, born in 1926, on the 8th of May is best known as a naturalist and as a broadcaster. Within his career, spanning over 60 years, he came to be known as one of the most popular experts on animals. He has penned and presented a natural history documentary which comprises a set of 24-disc DVD box set, which was named the Life Collection. This collection was released on 5th December in the United Kingdom and the episodes covering all domains of life like Life on Earth, The Living

Planet, The Trials of Life, and Life in the Freezer and throws light on The Private Life of Plants, The Life of Birds, The Life of Mammals, and the Life in the Undergrowth.

## Early Life

David Attenborough was born in Isleworth in Middlesex but was brought up on the campus of University College in Leicester. He thus spent his initial years in College House on the campus, and his father Frederick Levi Attenborough was the principal of the University College. Academy award-winning actor-director Richard Samuel Attenborough was his elder brother, and Alfa Romeo motor executive and then financial advisor John Michael Attenborough was his younger brother. Son of Frederick Attenborough and Mary Attenborough, David Attenborough is the second of the three sons and currently, the only one surviving.

Attenborough's fascination with nature has its origin in his formative years, which he spent collecting natural specimens, bird eggs, fossils, and stones. In 1938, during the build-up to the Second World War, Sir David's parents helped some of the many children fleeing from Germany. They have left their families behind and could bring almost nothing with them. One of them once gave Sir David a piece of amber that had some creatures embedded in it. Fifty years later, he wrote and presented the BBC documentary, *The Amber Time Machine* based on that.

In Leicester, Sir David was a student at the Wyggeston Grammar School for Boys and having secured a scholarship, he went on to pursue his degree in natural sciences as a student of Geology and Zoology from Clare College, Cambridge. In 1947, he did national service in the Royal Navy.

## Early Career

In 1950, David Attenborough worked in a training program at British Broadcast Corporation (BBC). The same year, he got married to Jane Elizabeth Ebsworth Oriell. He edited children's textbooks

after leaving the Navy before applying for his next job in BBC as a talk producer on the radio. He was rejected for the job but the head of Talks department of BBC, Mary Adams, got drawn into his CV and this soon gave Sir David his full-time job at BBC in the year 1952. He joined BBC at a time when there were almost no programs dedicated to natural sciences. Starting at such a juncture, he went on to embark on a multitude of projects, starting from a quiz show named *Animal, Vegetable, Mineral?* David Attenborough also worked on a folk music series named *Song Hunter*.

## Style and Nuances

Sir David was averse to the idea of deracinating animals from their natural habitats and transporting them to the harsh environment of TV studios. He pioneered the trend in filming animals by sending out crews into the wild to capture the images on location. Along with Sir David, Julian Huxley, another well-known naturalist, featured animals from the London zoo; explaining courtship, aposematism, camouflage, and their use. This three-part series named *Animal Patterns* was presented and produced by Attenborough, and it was through this studio-bound natural history program that David Attenborough met Jack Lester. Together, they made a series about an animal-collecting expedition, named *Zoo Quest*. Jack Lester was the curator of the reptile house of the zoo. This series was first broadcasted in 1954. The huge success of the show resulted in BBC establishing its Natural History Unit (David Attenborough n.d.).

In the early 1960s, Attenborough parted ways with the BBC, resigning from his permanent staff position in early 1960s to get his postgraduate degree in Anthropology from the London School of Economics. He joined BBC again, even before he could complete his degree, as the controller of BBC Two, the second flagship television channel of BBC.

He continued to be instrumental in making pioneering content with series such as *The Ascent of Man* and *Civilization*. In 1965, even though he was the controller of BBC Two, due to a clause in

his contract that allowed him to produce films, he was able to film Tanzania's elephants, while in 1969 he produced a series consisting of three parts on the Island of Bali in Indonesia depicting its cultural history. The following year, he was honored with Desmond Davis Award by British Academy.

He went to a New Guinea to a remote highland valley to seek out a lost tribe. This was for the television documentary *A Blank on the Map* released in 1971. Attenborough also helmed other famous series like *The Trials of Life*, *The Living Planet*, *The Life of Mammals*, *Life in the Undergrowth*.

Sir David changed the schedules as BBC Two was not doing very well. As a controller, he changed the mascot of the channel which was a quirky kangaroo and introduced programs related to drama, sports, science, natural history, entertainment, art, music, travel, archaeology, and even experimental comedy for viewing.

## Breaking New Ground

Some programs he commissioned are *The Old Grey Whistle Test*, a British music show, *The Money Program*, a finance and business affairs program, and many others like *Life*, *Monty Python's Flying Circus*, *Call My Bluff*, *Chronicle*, etc. Televised snooker and rugby league were introduced by Sir David as a controller when BBC Two became the first British television channel to broadcast in color.

BBC Two started offering an Ultra High-Frequency color television service. Sir David ordered a 13-part series to be made on Western art history. This decision was very significant. Another documentary series named "Civilisation" written and presented by Kenneth Clark was produced by BBC in 1969 that aired on BBC2. Attenborough, in 1969, controlled the output of both the BBC television channels as he had been promoted to the post of director of programs. He left his post and returned to program-making, which meant he had free time to invest in writing and presenting the natural history epic that he had planned. One of his landmark successes came

when his 96-episode program *Life on Earth* released, which employed advanced filming techniques, garnering hundreds of millions of viewers.

In the subsequent years, he produced a host of other series, aimed at documenting animal behavior. The 10-part series won him the Peabody Award. *Wildlife on One* aired from 1977 to 2005, having 250 episodes. Planet Earth was the first High-Definition show aired on BBC in 2006 and it is also the first extensive wildlife documentary ever made.

## Awards and Fame

Throughout his life, Attenborough has won several awards and accolades and has received immense fame and recognition. He was featured on a list of 100 great British heroes in a 2002 poll conducted by BBC, wherein people of Britain were asked to pick a person who, according to them, epitomized greatness. The list included scientists, inventors, and even royals. In 2006 Reader's Digest poll, he was named the most trusted celebrity. He was knighted in 1985 and holds several honorary degrees from British Universities. Several species of birds, animals, and insects have been named in Attenborough's honor. Some of them are *Pristimantis attenboroughi* (frog species from Peru), *Sitana attenboroughii* (fan-throated lizards found in coastal region of Kerala, India), *Sylvicanthon attenboroughi* (dung beetle from South America), *Euptychia attenboroughi* (butterfly), *Trigonopterus attenboroughi* (flightless weevil from Indonesia), Plesiosaur Attenborosaurus conybeare (type of prehistoric sea reptile) and *Zaglossus attenboroughi* (long-beaked echidna living in New Guinea) (Fossil named after Sir David Attenborough – BBC News [n.d.](#)).

## Views and Activism

In Blue Planet, his recent nature documentary on marine life, he portrayed the life-threatening consequences of anthropogenic activity on oceans

and in turn, the ecosystem. The series generated continuing large-scale awareness and garnered tremendous attention – a phenomenon termed the “blue planet effect” (The Attenborough effect [n.d.](#)). Andrew Dykes, founder of Global Sustainability Trust said that the effect created a trend of socially beneficial investments. The show even propelled Queen Elizabeth II to bring a ban on plastic bottles across the royal estates (“Blue Planet effect” gives boost to sustainable investment [2018](#)).

Sir David has been a staunch advocate of environmental causes both on and off screen and believes that the catastrophe of environmental destruction can be contained: “real success can only come if there's a change in our societies and our economics and in our politics.” In a 2018 interview, he said that the key to saving the planet is controlling the population. Speaking to delegates at COP24 held in Katowice, Poland, he said that humanity was in throes of a manmade disaster of global scale: climate change. “The Garden of Eden” is no more, he said, imploring the people and the leaders across the world to rise to the occasion and bring the pledges of 2015 Paris Climate deal to fruition (Carrington [2018](#)). In an interview with Prince Williams, Attenborough said that mankind could “wreck the natural world” but fortunately wields the power to live in harmony with nature (David Attenborough and Prince William take world leaders to task on environment | Environment | The Guardian [n.d.](#)). Attenborough is agnostic and believes that evolution best explains the diversity of life.

## On Animal Behavior

In the three-part documentary, Tiger-the spy in the jungle (2008), Sir David's team with the use innovative wooden spy cameras carried by elephants captured the intimate portrait of tiger's life. In this documentary, he showed the life of a tiger mother and her four cubs from Pench Tiger Reserve of India. In the same documentary, his team showed the day time foraging activity of the Sloth bear (*Melursus ursinus*) which are the most nocturnal

among the bears. His team showed the sloth mother carrying her young one on her back. Sloth bear is the only bear to carry its young on the back.

In his documentaries, Sir David has illustrated the behavior of many animals in a way that can be understood by the common man. Orangutan using axe on the wood log, nest building behavior of the Australian bowerbird, wild crows inhabiting the city and use it to their advantage in a Japanese city, mating ritual of hedgehogs, food sharing behavior of vampire bats, utilization of bioluminescence by animals, effect of cordyceps parasitic fungi on insects extraordinary hunting technique of bolas spider (orb-weaver spider), and Dam building behavior of beavers are a few examples.

## Books by Sir David

Sir David's documentaries are mostly accompanied by a book with the same name. The books by Attenborough are given below:

- Zoo Quest to Guyana (1956)
- Zoo Quest for a Dragon (1957)
- Zoo Quest in Paraguay (1959)
- Quest in Paradise (1960)
- People of Paradise (1960)
- Zoo Quest to Madagascar (1961)
- Quest Under Capricorn (1963)
- Fabulous Animals (1975)
- The Tribal Eye (1976)
- Life on Earth (1979)
- Discovering Life on Earth (1981)
- The Living Planet (1984)
- The First Eden: The Mediterranean World and Man (1987)
- The Atlas of the Living World (1989)
- The Trials of Life (1990)
- The Private Life of Plants (1994)
- The Life of Birds (1998)
- The Life of Mammals (2002)

## David Buss

David M. Buss

Department of Psychology, University of Texas at Austin, Austin, TX, USA

David Buss is one of the co-founders of the modern field of evolutionary psychology. He is widely known for his scientific contributions to understanding human mating strategies, subsumed under *sexual strategies theory*. He has made contributions to personality psychology, personality and social interaction, adaptive individual differences, tactics of manipulation, sexual conflict, stalking, sexual violence, and homicide. He authored or co-authored three other evolution-based theories: *strategic interference theory* (Buss 1989a), *error management theory* (Haselton and Buss 2000), and *homicide adaptation theory* (Buss and Duntley 1998; Duntley and Buss 2011).

In 1976 when Buss sought a PhD program, there existed no evolutionary psychologists and no field called evolutionary psychology. After receiving his PhD in 1981 from the University of California, Berkeley, in personality psychology, Buss accepted a position as Assistant Professor at Harvard University.

In 1984, Buss published his first paper on evolutionary psychology, entitled "Evolutionary Biology and Personality Psychology: Toward a Conception of Human Nature and Individual Differences" in *American Psychologist*. Although naïve and ill-informed in many ways, it signaled Buss's enduring commitment to understanding species-typical psychology and profound individual differences within a unified evolutionary framework.

In 1984, Harvard promoted Buss to Associate Professor, but he simultaneously received an offer from the University of Michigan of Associate Professor. Shortly after starting his position at Michigan, he and six other professors formed the *Evolution and Human Behavior* (EHB) group in 1986, funded with a generous internal grant from a prescient Dean. In 1986, Buss was

honored to Chair a symposium with the invited speakers Richard Alexander, W.D. Hamilton, George C. Williams, Mildred Dickemann, Martin Daly, and Napoleon Chagnon. Yearly meetings eventually led to the formation in 1989 of the *Human Behavior and Evolution Society* (HBES) with W.D. Hamilton serving as its first President.

In 1987, Buss was elected to be a Fellow at the *Center for Advanced Studies in the Behavioral Sciences* at Stanford. While there during 1989–1990, he co-led with Leda Cosmides a special project, "Foundations for Evolutionary Psychology," which included Martin Daly, John Tooby, and Margo Wilson.

## Evolved Mate Preferences

Buss launched a study of 37 cultures, involving 10,047 participants from six continents and five islands. The first wave of results was published in a target article in *Behavioral and Brain Sciences* (Buss 1989b). The findings that received the most attention were the discoveries of universal evolved sex differences. Men more than women valued cues to fertility. They placed greater importance on physical attractiveness. Appearance contains a bounty of cues to fertility. Men universally also desired younger spouses, supporting a second evolution-based prediction. Fertility is steeply age-graded among women, more so than among men, so youth is a powerful cue to fertility and future reproductive potential. Women more than men universally prioritized financial resources, economic prospects, and nearly universally prioritized cues that lead to resources, such as ambition/industriousness and social status.

These basic findings provided the first massive cross-cultural support for a key set of evolutionary psychological hypotheses. In 1989 when they were published, evolutionary hypotheses were widely regarded as speculative, lacking an empirical basis. These findings rendered that view no longer tenable. Those findings remain among the most robust psychological sex differences ever documented across cultures. It was an early

“success story” for the emerging field of evolutionary psychology and helped spur others to get into the field. The study became a “citation classic” and as of 2019 has received roughly 5,000 scholarly citations.

### **Tactics of Mate Competition: Mate Attraction and Competitor Derogation**

According to sexual selection theory, the mate preferences of one sex should establish the ground rules for intrasexual competition in the other. Buss developed the first taxonomy of tactics of mate attraction, which includes 23 distinct tactics, including displays of kindness, devotion, resources, grooming, physical strength, and so on (Buss 1988a; Schmitt and Buss 1996). These studies also discovered unpredicted tactics, such as the display of humor, a topic that has subsequently received much research attention and theorizing.

Because mate competition is a zero-sum game in which one person’s gain in mating comes at a loss to a rival, one can conceive of two general strategies – enhancing one’s own attractiveness relative to rivals (tactics of attraction) and rendering rivals less attractive to mates relative to oneself. This logic led Buss to conduct the first empirical studies of derogation of competitors – the tactics that people use to impugn the desirability of their rivals. He developed the first taxonomy of derogation of competitor tactics, which included 28, such as questioning a rival’s fidelity, spreading false rumors about sexually transmitted infections, derogating a rival’s intelligence, and questioning a rival’s sexual orientation (Buss and Dedden 1990). The studies supported the evolution-based predictions about sex-differentiated tactics. Men more than women derogated their rival’s resources (e.g., “He drives a poor car”) and physical prowess (e.g., “He told others that his rival was physically weak”). Women more than men derogated their rival’s physical appearance (e.g., “She made fun of the size and shape of her rival’s body”) and ability to remain sexually loyal (e.g., “Told others that her rival slept around a lot”).

### **Tactics of Mate Retention**

Mates gained must be retained to reap the reproductive potential inherent in long-term mate selection. Buss launched the first set of studies on tactics of mate retention in dating couples and married couples, as well as the first taxonomy of mate retention tactics (Buss 1988b; Buss and Shackelford 1997). Tactics ranged from *vigilance* (e.g., “He called her at unexpected times to see who she was with”) to *violence* (e.g., “He hit the guy who made a pass at his girlfriend”).

### **Mate Poaching Tactics**

Mate poaching – attempting to lure someone who is already in a mating relationship for either a short-term sexual encounter or a long-term relationship – turns out to be quite common (Schmitt and Buss 2001). Together with David Schmitt, Buss conducted the first studies of human mate poaching and developed a taxonomy of its main tactics. Many tactics turned out to be similar to tactics of attraction. But some are unique to the mate poaching contexts, such as befriending the couple in a platonic guise. Another is derogating one partner to the other (e.g., “He doesn’t appreciate you” or “You are too good for him”), implying a mate value discrepancy. Mate poaching represents a domain previously unexplored prior to the Schmitt and Buss (2001) study, and the term “mate poaching” has now entered the mainstream scientific lexicon ([http://tierneylab.blogs.nytimes.com/2009/08/27/why-poach-anothers-mate-ask-an-expert-or-brangelina/?\\_r=0](http://tierneylab.blogs.nytimes.com/2009/08/27/why-poach-anothers-mate-ask-an-expert-or-brangelina/?_r=0)).

### **The Emotion of Jealousy**

Jealousy is a commonly experienced emotion in romantic relationships. Yet it was largely ignored by emotion researchers. Buss sought to test hypotheses about the functional design of jealousy. He collaborated with Drew Westen, Randy Larsen, and Jennifer Semmelroth, and together, they discovered strong evidence for hypothesized sex differences in the weighting given to triggers

of jealousy. They posited that emotional infidelity was a cardinal cue to the loss of a partner's commitment for women, whereas sexual infidelity was a key cue to compromised paternity certainty. Although both sexes clearly become upset about both sexual and emotional infidelity in a partner, when forced to choose which is more upsetting the predicted sex differences emerged. Moreover, men showed greater physiological distress to imagining a partner committing sexual infidelity, whereas women showed greater physiological distress to imagining a partner committing emotional infidelity (Buss et al. 1992).

### Strategic Interference Theory

Buss saw the functional emotion of jealousy as part of two larger theories. The first was strategic interference theory (Buss 1989a). He proposed that emotions such as jealousy, anger, and upset become activated when a person's strategy for achieving a goal was impeded or blocked. A strategy of securing a partner's sexual fidelity, for example, was impeded by attempts by mate poachers or rivals trying to lure one's partner for sex or romance. To take another example, a woman's strategy of exercising "female choice" about when and with whom she consents to having sex would be impeded by a man who pursued a strategy of sexual force or aggression. Strong negative emotions such as anger, jealousy, and upset serve several key functions, according to strategic interference theory: (1) they alert someone to the source of the interference, (2) motivate action to curtail the interference, and (3) help to store interfering events in memory, which in turn functions to (4) avoid future episodes of strategic interference.

### Error Management Theory

Jealousy turned out to be illuminated by error management theory (EMT), originally developed by Martie Haselton, Todd DeKay, and Buss (Haselton and Buss 2000). EMT is a theory of selection, so can be applied to any domain of

psychology from perception to social interaction. EMT logic can be stated syllogistically: (1) we live in an uncertain world; (2) we experience cues that are only probabilistically related to cost-inflicting or benefit-bestowing events; (3) there are two ways to err – by inferring the existence of an event when it has not in fact occurred and by inferring the nonexistence of an event when it in fact has occurred; (4) if there are recurrent cost-benefit asymmetries in making these two types of errors, selection will favor adaptively biased inference procedures that function to minimize committing the more costly error, even at the cost of experiencing more frequent inferential errors of the less costly variety.

Jealousy illustrates EMT logic. Buss argued that the cost of missing a sexual infidelity that has occurred is typically greater than the cost of mistakenly suspecting an infidelity when none has occurred (Buss 2000). Because infidelities are typically conducted underneath a cloak of intentional secrecy, their existence must be inferred from probabilistic cues. Empirical evidence supports EMT logic applied to jealousy and infidelity (e.g., Buss 2000). Haselton and Buss also used EMT to illuminate design features of the male sexual over-perception bias and the female commitment skepticism bias (Haselton and Buss 2000). EMT logic has been used to illuminate a raft of other psychological phenomena, such as the auditory looming bias, the vertical descent illusion, and adaptive biases in a number of domains of social functioning. EMT logic has also been invoked to explain inferential biases about homicidal intent (Buss 2005).

### The Evolution of Aggression and Murder

Because differential reproductive success necessarily hinges on reproductive competition, conspecifics are necessarily rivals, albeit in the context of some levels of intertwined reproductive fates and win-win situations ("gains in trade") that select for adaptations for cooperation in certain contexts. Enhancing oneself relative to rivals is one generic strategy. A second is inflicting costs on rivals. Buss documented these two generic

strategies in the context of mate competition – tactics of attraction and derogation of competitors. In collaboration with Joshua Duntley, Buss extended this argument to murder. They argued, contrary to the Daly-Wilson claims that murder is a by-product of adaptations designed for nonlethal ends (Daly and Wilson 1988), that humans have adaptations for murder (Buss 2005; Buss and Duntley 1998; Duntley and Buss 2011).

Homicide adaptation theory (HAT) proposes that humans have evolved a number of distinct homicide adaptations, such as infanticide, intrasexual rival murder, and coalitional killing (warfare). Simply put, killing a rival, killing a rival's offspring, or killing a rival's kin has been extremely an effective way of inflicting massive fitness costs on intrasexual competitors. The accumulating evidence of adaptations for conspecific killing in chimpanzees leads to the conclusion that some of these homicide adaptations predate the evolution of *Homo sapiens*.

Buss and Duntley believe that there is sufficient evidence – from the paleontological skulls and skeletons riddled with unmistakable marks of murder to the psychological and behavioral footprints of “special design” for murder – to conclude that it is far more likely than not that humans have experienced a long coevolutionary arms race that created adaptations for murder and defenses to prevent being murdered.

## Authored Books

In an effort to reach a broader audience for evolutionary psychology, Buss has authored several books. These include *The Dangerous Passion: Why Jealousy Is as Necessary as Love and Sex* (2000), *The Murderer Next Door: Why the Mind Is Designed to Kill* (2005), and *Why Women Have Sex* (2009; co-authored with Cindy Meston). His two most influential books are *The Evolution of Desire: Strategies of Human Mating* (1994, 2003, 2016) and *Evolutionary Psychology: The New Science of the Mind* (1998, 2004, 2008, 2012, 2015).

*The Evolution of Desire*. This book represented the culmination of a decade of research by Buss

and a conceptual synthesis of hundreds of studies on human mating by other scientists. It elaborated on sexual strategies theory (Buss and Schmitt 1993) and included chapters on what women and men wanted in long-term and short-term mates; strategies of casual sex; tactics of attraction; causes of sexual conflict and breakups; mating over the lifespan; and harmony between the sexes. The book was first published in 1994; two new chapters were added to a new edition published in 2003; and the book was totally revamped in a thoroughly updated and revised edition, published in 2016. It has been translated into ten languages and continues to be widely used in college courses worldwide.

*Evolutionary Psychology: The New Science of the Mind*. While evolutionary psychology began to emerge as a cogent metatheory for psychology in the late 1980s and early 1990s, professors began to offer courses in it. There existed no textbook. One was urgently needed. After getting encouragement from a handful of people to write such a text, and being approached by publishers, Buss signed a contract. He produced the first textbook in the field in 1998. The text provided historical reviews of evolutionary theory and psychological science that converged on their synthesis (Chapter 1) and a chapter on the conceptual foundations of this new science of the mind, heavily influenced by the theoretical work of Leda Cosmides and John Tooby (Chapter 2). Subsequent chapters were organized logically around adaptive problems – challenges of survival, mating, parenting, kinship, and social group living (e.g., cooperation, aggression, status hierarchies). The final chapter called for the evolutionizing of all subdisciplines within psychology, such as cognitive, social, personality, developmental, and clinical; reviewed evolutionary empirical work within each; and ended with a call for a unified field of psychology that eventually could dissolve these somewhat artificial subdisciplinary boundaries.

Through this text, Buss helped the field of evolutionary psychology to grow and flourish, educating undergraduates, informing professors, and attracting new scholars to the field.

## Edited Volumes

Buss has edited six volumes, including *Personality Psychology: Recent Trends, Emerging Directions* (Buss and Cantor 1989), *Biological Approaches to Personality* (Buss 1990), *Sex, Power, Conflict: Evolutionary and Feminist Perspectives* (Buss and Malamuth 1996), and *The Evolution of Personality and Individual Differences* (Buss and Hawley 2011). His most influential edited volume, however, is *The Handbook of Evolutionary Psychology* (Buss 2005), logging in at more than 1,000 double-column pages and some 35 chapters. This led to a 2nd edition of the *Handbook* (Buss 2016), which expanded to more than 50 chapters. Both editions contained a Foreword by Steven Pinker, a special essay by Don Symons, and an Afterword by Richard Dawkins.

## Teaching and Mentoring PhDs in Evolutionary Psychology

Throughout his career, Buss has devoted considerable effort to mentoring the future generation of scientists. Of his 27 PhD students, roughly two-thirds have obtained tenured or tenure-track professorial positions. The Association of Psychological Science (APS) honored Buss with the *2017 Mentor Award for Lifetime Achievement*. His former students such as Todd Shackelford, Martie Haselton, and David Schmitt, in turn, have produced a number of PhDs in evolutionary psychology and themselves have made major contributions to the field.

David Hume (1711–1776) is considered one of the most important philosophers of the United Kingdom, since his philosophical, political, and economic works have permeated an important part of modern thinking.

## About His Life

Hume was born on April 26, 1711, in Edinburgh, Scotland. His father's family is a branch of the Earl of Hume, and his mother was the daughter of Sir David Falconer (President of the College of Justice). However, his family had little economic power, and as the youngest son, his patrimony was small. His father died when he was still a baby; his mother had to take charge of the upbringing, basic education, and religious training of him and his two siblings (Hume 1826).

He showed great interest in studies from a very young age, because of which his family considered that he should become a lawyer; however, Hume considered everything except the study of philosophy and knowledge in general to be aberrant. Unfortunately, his economic resources were not sufficient for his life plans; thus, at age 23 he began working in Bristol as a merchant, while increasing his knowledge of literature and

philosophy. After just a few months, he went to France, where he decided to dedicate himself exclusively to his studies, living and eating frugally to make his little money last. In this period he wrote his first work, the *Treatise on Human Nature*, which was published in London in 1738. Although it is now considered one of his greatest works, it did not achieve great distinction at the time (Hume 1826).

After this first publication he returned to his family's house in Edinburgh, where he began to write and publish his first works on morals and politics, which were well received. As he mentions in his autobiography, in 1745, after receiving an invitation from the Marquis of Annandale, Hume served for a year as his tutor, since the health and mental state of that young nobleman required it. He then received an invitation from General St. Clair to act as secretary in an expedition, and later to serve him in his military embassy in the courts of Vienna and Turin. Although his studies stopped during these years, he increased his capital considerably (Hume 1826).

Wishing for better success of his first work, while still in Turin he re-issued the first part of the *Treatise on Human Nature* as *An Enquiry Regarding Human Understanding*, which at first did not have much more success than the initial publication. After this he lived with his brother in the family house in Edinburgh for two years, where he wrote *Political Discourses* (1752), and republished the second part of his first work as *An Enquiry Concerning the Principles of Morals* (1752), while his other writings were attracting the attention of intellectuals (Hume 1826).

Hume moved from the country to the city in 1751, where he became the librarian of the Faculty of Advocates at the University of Edinburgh. During this time he began to write about the history of Great Britain, as well as the natural history of religion and other smaller texts. The great success of his writings allowed him to accumulate considerable money, thus he returned to his native city with the intention of stopping all activity; however, he began to receive work offers from several nobles, which he did not reject. He returned definitively to Edinburgh in 1769, where he remained until his death on August 25, 1776, as a result of a gastrointestinal disease (Hume 1826).

## Hume's Treatise of Human Nature

Hume is one of the so-called British empiricists, who postulated that human knowledge comes from experience. The ideas that Hume put forward in the *Treatise on Human Nature* (and the books derived from it), in which he expressed his theory on the content and functioning of the mind, were a great contribution to this movement. Many authors have recognized this as a consequence of an epistemological, ontological, and methodological viewpoint of the phenomena studied (Stepukonis 2019).

According to Hume, the perceptions and contents of the human mind may be classified as *simple* or *complex*. Complex perceptions are those which can be decomposed into multiple elements; for example, a forest may be composed of trees, soil, and rocks; there are also different color, odors, and sounds present. One of the main divisions Hume makes to understand the perception of the mind is that of *impressions* and *ideas* or *thoughts*; both may be simple or complex. One of the main differences is that impressions are experienced more strongly and vividly than ideas or thoughts. This is because impressions are those which are experienced when the senses are capturing the objects, while ideas or thoughts come from the impressions and are experienced once the objects are not present, and often become weaker when there is more distance between these objects (Hume 1960, 1999).

Impressions are separated into two classes: *sensation* and *reflection*. Impressions of sensations are those which excite the senses, allowing us to receive colors, sounds, heat, thirst, hunger, pain, or pleasure. These impressions produce an idea or thought which remains after the impression has ceased. When objects are again presented to the senses, the ideas of pleasure or pain generate the impressions of reflection, which are those of passions and emotions (e.g., desire, aversion, hope, fear), for which the corresponding ideas will be created (Hume 1960).

Ideas may be classified as *memory* when impressions are recalled, both simple (e.g., the color red, happiness) and complex (e.g., an entire city, amorous passions), and *imagination*, complex ideas for which there has been no

experience as such, but there are impressions of its simplest parts. An example of imagination can be the idea of a Pegasus, which is formed by the ideas of horses and of wings, or by imagining an ancient city with the descriptions provided by writers. Hume also affirms that there are moments when memory and imagination mix (e.g., when we don't remember all the facts, the imagination can act to supplement the memory); the only limit to imagination is that it cannot create simple ideas for which there is no experience, such as new colors, sounds, or passions. For this reason, Hume reached the conclusion that the best way to know if an idea is real or fictitious is to find its corresponding impression (Hume 1960, 1999).

Hume believed that ideas are mainly associated by three connecting principles: (1) *space-time contiguity*, since one idea may evoke another if they are united in time and space (e.g., sand and sea, coffee and cream); (2) *similarity*, when two or more ideas may be compared, either by their similarity or difference; and (3) *cause and effect relations*, with which what will happen or has happened may be inferred. For example, if we observe a campfire we may infer that soon only ashes will be left, and conversely, if we observe ashes, we may infer that there was a campfire in this place. However, Hume observed a problem in cause-effect relations. Although we observe that fire burns wood and leaves ashes when it extinguishes, the fire, heat, and later ashes are what the impressions capture, but it is not possible to capture the "power" that the cause has to produce the effect, and also the cause and effect often are not similar (Hume 1960, 1999).

According to Hume, the idea of cause and effect is generated due to the principles of contiguity and similarity. For cause and effect to be established as such, the cause must be followed by the effect, thus these must be united contiguously in time and space, and this connection must also happen recurrently (regularity). Once we notice that eating an apple (cause) is sweet and nutritious (effect), the similarity that this apple has with others will make us expect the same effect by eating other apples; while if we observe a difference between one apple and another, it is expected that the effect will also change proportionally,

thus forming a habit or custom (Hume 1960, 1999).

Hume observed a close relation between space and time, since we cannot perceive one without the other, and recognized that these relations have behaved regularly in the universe, giving origin to the habit that maintains the cause-effect relation, but given that we have neither experience nor impressions of the future, nothing can assure that these regularities will be maintained, due to which he classified the cause-effect relation as a belief (Hume 1960). This reasoning is also extended to the *substance/essence* of objects, the soul and the idea of God, given that these elements cannot be perceived by the senses and also does not come from an impression of reflection (Hume 1960).

The extreme of the relevance that Hume gave to the senses may be seen in his idea of *morality*, which would also come from experience. When we perceive that something does good for someone, the impression of well-being or happiness is generated, while when we observe that some behavior does bad to the other, we generate an impression of discomfort or bother. Hume thus suggests that what is morally correct should be based on these impressions (Hume 1960).

Hume's ideas on human nature have had a strong influence on other important philosophers such as Kant, who added to the discussion on human knowledge (De Boer 2019), and positivist epistemologists such as Popper, who take into account the problem of the cause-effect relation (Wettersten 2016), and have also influenced experimental psychology and learning theories (Waldmann et al. 2006), establishing the bases to understand associative processes.

## David Premack

Crickette Sanz<sup>1</sup> and Jake A. Funkhouser<sup>2</sup>

<sup>1</sup>Washington University in St. Louis, Saint Louis, MO, USA

<sup>2</sup>Central Washington University, Ellensburg, WA, USA

## Introduction

David Premack was a prolific scholar who made major theoretical contributions, advancing the study of many comparative psychological topics. Following the cognitive revolution, he

successfully traversed the transition from his focus on behaviorism to become an active cognitive theorist and investigator. Within behaviorism, he proposed reversibility of the reinforcement relation. Later in his career, Premack raised the question of chimpanzees having a theory of mind; this early questioning has since inspired decades of research. Premack's ingenious experiments and creative approaches are widely acclaimed and serve as examples to many aspiring comparative psychologists.

## Background and Contributions

David Premack (October 26, 1925, to June 11, 2015) was an American psychologist who achieved empirical and theoretical excellence in advancing studies of associative learning and comparative cognition. He received his academic training at the University of Minnesota, obtaining a Bachelor of Arts degree in chemistry and liberal arts in 1943, a Master of Arts degree in Experimental Psychology and Statistics in 1951, and a doctoral degree in Experimental Psychology and Philosophy in 1955. He first began conducting primate research in 1954 at the Yerkes Primate Biology Laboratory in Orange Park, Florida. He held faculty positions at University of Minnesota, University of Missouri at Columbia, University of California at Los Angeles, University of California at Santa Barbara, and Harvard University. In 1990, he retired as professor emeritus of psychology from University of Pennsylvania.

### Premack Principle

By demonstrating that reinforcers were more relative and dynamic than previously considered, Premack challenged the traditional absolute value of reinforcers (Premack 1959). For any pair of responses, he asserted that the more probable response would reinforce the less probable response. He predicted that the responses themselves were reinforcing and the relation between them was reversible (Premack 1962). By testing this principle, it was demonstrated when more probable behaviors are made contingent upon less probable

behaviors, less probable behaviors are more likely to occur. Informally, this had already been widely applied by making a desirable "reward" (such as playing a game) contingent upon the occurrence of a less desirable behavior (such as completing a chore), this contingency increases the overall likelihood of the less desired behavior's exhibition. The Premack Principle stands as a major contribution to the psychology of learning.

### Theory of Mind

Premack and Woodruff (1978) introduced the concept of "theory of mind" as an individual's ability to impute mental states to one's self and others. As many others began investigating theory of mind in nonhuman apes, Premack and Woodruff presented Sarah (a female chimpanzee with experience in laboratory and language training) with video recordings of human actors attempting to solve various problems but encountering obstacles, they then assessed Sarah's ability to choose photographs of appropriate alternative solutions. Their results indicated that Sarah understood the problem, the human actor's purpose, and chose alternatives compatible with that purpose. Premack followed this initial research with innovative experiments to examine chimpanzee attention and intentions, as well as one's understanding of others' knowledge and beliefs. Subsequent to these early investigations, the ability of an individual to infer the mental states of others has been an active area of research and debate among scholars.

### Effects of Enculturation

In *The Mind of an Ape*, David Premack and his wife Ann Premack (1983) describe teaching several chimpanzees to use a token-based language system. They noticed marked performance differences across other cognitive tests by chimpanzees that were trained to use this form of symbolic communication compared to those that were not. Premack (1983) suggested exposing chimpanzees to enculturated language training could improve their abilities in abstract judgment. In particular, he discussed enhanced use of an abstract propositional code could improve their abilities to

represent and judge relations. Premack's discussions on chimpanzee enculturation and symbolic language were important contributions to investigations of cognitive ability. Relative to other ape language studies of this time, Premack was one of the first to relate an individual's abilities with past experience and learned cognitive skills.

### Human and Animal Cognition

Based on extensive comparative studies of intelligence (such as Premack 1976), Premack suggested that human and animal cognition had different evolutionary origins (Premack 2007). Human cognitive abilities are domain-general, serving many goals, whereas animal cognition represents more limited adaptations, serving a single goal. Although there are similarities, Premack rejected equivalence between animal and human cognition. He cited enduring differences in the domains of teaching, short-term memory, causal reasoning, planning, deception, transitive inference, theory of mind, and language. Throughout his career, Premack attempted to synthesize the evolutionary significance of his comparative research. For example, he thoughtfully contextualized the ape language studies (Premack 1983) and addressed the anthropological implications of cognitive differences between humans and apes (Premack and Premack 2003).

### Conclusion

David Premack's research and legacy continue to have a major impact on psychological research. In recognition of his academic achievements, he was awarded the Fyssen Foundation International Research Prize in 1988, the Medal of the College de France in 1991, and the William James Fellow Award by the American Psychological Society in 2005.

### David Washburn

Duane M. Rumbaugh<sup>2</sup> and David A. Washburn<sup>1,2</sup>  
<sup>1</sup>Covenant College, Lookout Mountain, GA, USA  
<sup>2</sup>Georgia State University, Atlanta, GA, USA

David Alan Washburn (October 5, 1961–) is an American experimental psychologist known for studies of attention, learning, and other cognitive processes in rhesus monkeys and human adults. He is an Emeritus Professor of Psychology and Neuroscience at Georgia State University, former chairperson of its Department of Psychology, and retired as Director of its Language Research Center. He is currently a Professor of Psychology at Covenant College.

### Personal and Professional History

David Washburn was born in Birmingham, Alabama, USA to Earl Derward and Constance Joan Washburn. He has one sibling, a younger

sister named Karen Renee. In 1970, the Washburn family moved to Smyrna, Georgia, where David would spend most of his childhood. His youth and adolescent years were primarily filled with church activities, sports, and reading. Deeply religious even as a child, David was enrolled in Smyrna Christian Academy for his junior high and high school years, and graduated in 1980 as valedictorian of a graduating class of just five seniors!

Washburn became interested in counseling in the 7th grade, and so enrolled as a psychology major at Covenant College, located just one mile inside the Georgia border, near Chattanooga, Tennessee. Covenant is a small liberal-arts college affiliated with the Reformed Presbyterian Church, and offered a psychology curriculum, in-state tuition, the opportunity to play junior-varsity soccer, and a spectacularly scenic campus perched atop Lookout Mountain. The college's most recognizable building is the so-called castle in the clouds, originally constructed as a luxury hotel, but the psychology department itself occupied the loft floor of what had once been a stable for the hotel. The "psych barn" housed a classroom, several laboratory rooms, a vivarium, and offices for the two faculty members in the psychology department. Douglas R. Sizemore had earned his Ph.D. (1974) from Northern Colorado University in statistics, which was the primary subject he taught during those years at Covenant. Michael J. Rulon is a general experimental psychologist who earned his Ph.D. (1975) working with D. D. Wickens at the Ohio State University. He was department chairman, and taught the bulk of psychology courses (including General, Developmental, Learning, Physiological) including several innovative offerings that would dramatically reshape Washburn's interest. One such course was called "Psych Tour." To give psychology majors at Covenant and similar small schools exposure to the breadth and depth of the discipline, Dr. Rulon organized summer road trips to some part of the country, where the students would travel by van from school to school, reading about the psychological work taking place at each, visiting laboratories or clinics, and interviewing prominent psychologists. Because Washburn knew he wanted to major in psychology when he arrived

at Covenant, he was able to take many required courses his freshman year, and registered for Psych Tour the following summer. The intensive 3-week course featured visits with many psychologists from San Francisco to Los Angeles, including memorable visits with Drs. James Dobson, Richard Gorsuch, Ernest Hilgard, Arthur Jensen, Bruce Narramore, Robert Ornstein, Karl Pribram, Warren Brown, a sleep lab, an EEG lab, a biofeedback lab, and much more. Washburn had entered Covenant to learn more about counseling troubled teenagers, but by the end of his first year he was completely committed to psychological science and the study of learning and other behavior.

In those days, every General Psychology student at Covenant adopted a rat and learned the principles of conditioning by completing exercises using psychology's operant chambers. Washburn's work-study assignments throughout his time at Covenant included animal care, maintaining the Skinner boxes, and helping new students to shape their animals. It was in this latter role that David, then a senior, met freshman psychology student Catherine Childs. The couple would marry in 1984, and often recount that they were introduced to one another by a laboratory rat.

Before graduating with his B.A. in psychology, Washburn spent a year as a transient student at Georgia State University, where he took additional psychology coursework and volunteered in the cognitive research laboratory of R. Thompson Putney. Putney had earned his Ph.D. (1966, Missouri) working with Robert S. Daniel, who had in turn been a student of Indiana University psychophysiological R. C. Davis. Washburn would return to Georgia State for graduate study, after being accepted into the Psychological Sciences doctoral program to work with Dr. Putney. Professor Duane M. Rumbaugh, chairman of the psychology department, phoned to convince David to return to GSU and to offer an assistantship as a computer programmer for the Language Research Center (LRC), where Rumbaugh was the founding Director. With a new Commodore-64 computer in hand and some knowledge of the BASIC programming language, Washburn returned to Atlanta to write game-like computerized tasks, on which the LRC apes (Lana, Sherman, Austin,

Kanzi) would respond by manipulating a joystick so as to control a cursor on the screen. His own research was conducted with humans as part of the memory research in Dr. Putney's laboratory.

In those days, Dr. Rumbaugh or Dr. Sue Savage-Rumbaugh would periodically invite Washburn to collaborate on a research project with the chimpanzees; however, he consistently declined, insisted that his intention was to study human cognition, preferring to program for other people's studies than to establish the intensive social relationships required for working with the apes. This changed in 1986, however, with the acquisition of two rhesus monkeys (Abel and Baker) at the LRC. When the Animal Welfare Act was amended that year to require researchers to "provide a physical environment adequate to support the psychological well-being of nonhuman primates" (United States Code, Title 7, Chapter 54, Section 2143, a.2.B), primate researchers around the country scrambled to understand how best to promote and to assess psychological well-being. With cognitive enrichments like the ape-language keyboards and game-like computer tasks, the LRC was well positioned on this issue. Accordingly, it was logical that Duane Rumbaugh would be consulted by groups like the National Aeronautics and Space Administration (NASA) for guidance on how to provide enrichment for the monkeys that they were studying – and were planning to study aboard the Space Shuttle. Although he knew that rhesus monkeys might not be able to master the remote cause-effect relations required to use the game-like computer tasks written for the chimpanzees, Rumbaugh reasoned that the benefits would be great if the monkeys could be successfully taught to use the joystick test system. NASA agreed to fund a feasibility project to investigate this possibility.

Washburn and fellow doctoral student William D. (Bill) Hopkins were invited to join a research team that included Drs. Duane Rumbaugh, E. Sue Savage-Rumbaugh, and Kirk Richardson. Although Washburn was hesitant, Rumbaugh argued convincingly that training the monkeys would not require the physical and social intensiveness of chimpanzee testing, but rather would be much more like testing human participants, or even

rats in operant chambers. If the monkeys could be shaped to manipulate joysticks (or to use touchscreens, as the project began with two monkeys learning the joystick and one monkey, working with Dr. James King in Arizona, using a touchscreen), then all subsequent training and testing of the animals would be automated. Some additional negotiation with Rumbaugh ensued, but the end result was Washburn and Hopkins sharing an "office" with rhesus monkeys Abel and Baker, and working to determine whether the monkeys could learn cursor-control skills.

The monkeys' success in mastering the computer test system resulted in a flurry of publications and a new comparative focus to Washburn's nascent research program (e.g., Washburn et al. 1989a, b). Whereas his M.A. thesis (1987) was an examination of functional cerebral asymmetries in undergraduate students' recognition of the chimpanzees' visuographic language symbols (called lexigrams), his dissertation for the Ph.D. (1991) was a comparative study of the effects of stimulus movement on macaques' and humans' attention, learning, and memory (Washburn 1993).

By the time Dr. Washburn earned his Ph.D., the NASA-funded behavior and performance project had grown from a demonstration study on psychological well-being to a central component of the international research collaboration on the effects of spaceflight on rhesus monkeys' physical and psychological health. The LRC research team was preparing for a Shuttle flight in which rhesus monkeys, from a colony of macaques at the NASA-Ames Research Center being joystick-trained under Washburn's supervision, would fly as payload for 2 weeks, performing a range of game-like computer tests before, during, and after the mission. Rather than leave before this spaceflight, Dr. Washburn remained at the LRC in a postdoctoral position. By the time the project actually flew in space in 1996 (aboard a Bion Russian biosatellite rather than the Space Shuttle; Washburn et al. 2000), Washburn had additional grants of his own that kept him in Atlanta and at the LRC. Among these awards were a series of grants from various Department of Defense agencies as a principal investigator (1992–2000) at the Center of Excellence for Research on Training at Morris

Brown College, a historically black college in Atlanta.

On the strength of this productive and well-funded research program, Dr. Washburn was appointed a Georgia State University faculty member at the rank of Academic Professional in 1996. In 2001, he moved to the tenure track as Associate Professor of Psychology, and was promoted to Professor with tenure in 2005. The following year he began a 4-year term as psychology department chair.

Duane Rumbaugh retired from Georgia State University in 2001, and David Washburn was appointed as the LRC's second Director. Under his leadership, the LRC secured continued support through a series of program-project grants from the National Institute of Child Health and Human Development, and saw growth in its team of investigators (faculty, staff, and graduate students), its physical space and resources, and its resident-animal colony. With respect to nonhuman primates, the LRC provided continuing care and stewardship of chimpanzees Lana, Mercury, and Panzee until their respective deaths; facilitated the transfer of Kanzi and his family of bonobos to the Great Ape Trust (now Ape Cognition and Conservation Initiative) in Iowa; and acquired multiple groups of capuchin monkeys to support the growing research program with those animals.

## Significant Contributions

In addition to his leadership of this internationally recognized research center, Dr. Washburn is best known for his role in developing and promoting the LRC's computerized test system (also known as the video-task system, the psychomotor test system, and the Rumbaughx; Rumbaugh et al. 1989; Washburn et al. 2012) for comparative cognition research. The apparatus has been used with a wide range of primate species, and with other animals ranging from pigeons and rats to bears and elephants. Washburn and others have also reported data showing that it serves, as originally intended, as an environmental enrichment that supports the psychological well-being of nonhuman primates (Washburn 2015).

Dr. Washburn's other contributions to the literature largely pertain to the topic of attention and its relation to other cognitive constructs. His studies with human and nonhuman primates of the stimulus movement effect, Stroop-like effects, visual search, and similar attention-related phenomena have illuminated the competition between stimulus control and cognitive control in attention and behavior (e.g., Washburn 1993, 1994, 2016).

Washburn has also contributed to the comparative-cognition literature on relational versus associative learning, reflecting the long-time collaboration with Duane Rumbaugh, and featured in their coauthored book, *The Intelligence of Apes and Other Rational Beings* (2003). His interest in relational learning (and why it sometimes fails to emerge) is also reflected in studies of numerical cognition, metacognition, and memory – research that benefitted from extensive collaboration with many of the most outstanding scholars in the field of comparative cognition, particularly Michael Beran, William Hopkins, and J. David Smith. Many of these collaborators contributed chapters to *Primate Perspectives in Behavior and Cognition* (2007), edited by Dr. Washburn and based on a festschrift in Duane Rumbaugh's honor.

Dr. Washburn served as President of several regional and national scholarly organizations (Southern Society for Philosophy and Psychology, Society for Computers in Psychology, Southeastern Psychological Association, and Divisions 3 and 6 of the American Psychological Association). He is a Fellow of the Society for Experimental Psychology and Cognitive Sciences, the Society for Behavioral Neuroscience and Comparative Psychology, the Association for Psychological Science, and the Psychonomic Society and has been recognized with awards from the Southern Society for Philosophy and Psychology, Psi Chi, the American Psychological Association, and Georgia State University.

## Dawn Singing

- [Dawn Solo/Chorus](#)

## Dawn Solo/Chorus

Jennifer R. Foote

Department of Biology, Algoma University, Sault Ste. Marie, ON, Canada

## Synonyms

[Dawn song](#); [Dawn singing](#)

## Definition

The dawn chorus is a period of vocalization that occurs during twilight before the sun rises.

## Introduction

The dawn chorus is a prominent acoustic display that begins during the twilight period characterized by a high rate of vocalization by many species. Whereas the most studied species are birds, mammals, insects, and anurans also may chorus at dawn. The focus of the entry is on birds with a

summary of other species at the end. The order in which participating species begin to chorus is predictable. In resident species, the dawn chorus may occur year-round, whereas, in migratory species, the dawn chorus begins within the first weeks following arrival on the breeding grounds.

## Research on the Dawn Chorus

Due to the striking nature of the cacophony of chorusing species at daybreak, the dawn chorus has been described historically for its beauty. Research on the dawn chorus began in earnest in the 1900s with efforts to characterize the timing and composition. In the 1970s, functional hypotheses began to be explored; yet, little progress was made initially due to the difficulty of recording the complex display. With the advent of new recording techniques and the ability to easily and quickly produce large numbers of sonograms, studies of the dawn chorus have proliferated.

Studies at dawn use a mix of observational and experimental approaches. Observational approaches involve describing the timing of the chorus and the rate and type of songs produced. Observational studies traditionally involved transcribing the chorus start time and the properties of choruses of individuals in the field. Currently, most observational studies also use field recordings, which include both focal recordings of individual birds using a directional microphone and recordings of the entire chorus using omnidirectional microphones, often in association with automated recording units. Experimental techniques include using song playback, mate or neighbor removal, food supplementation, or physiological manipulations.

## Environmental Factors

In most cases, the start of the dawn chorus closely tracks the increasing light levels during the twilight period; however, in other species, the timing of song may drift further from twilight towards the middle of the breeding season (Leopold and

Eynon 1961). At northern latitudes, with nearly continuous daylight, the chorus may instead track the time when light intensity is at its lowest value (Brown 1963). Factors that influence the light level detected thus influence the timing of the chorus (e.g., Thomas et al. 2002). Meteorological conditions that may inhibit sound transmission or cause energetic stress have been shown to influence both dawn chorus timing and song output (e.g., Bruni et al. 2014). Henwood and Fabrick (1979) modelled environmental conditions at different times of day and determined the early morning (dawn) is optimal for sound transmission though empirical support for improved acoustic transmission is mixed. Noise at dawn can also influence the timing of the chorus, for example, urban noise can result in earlier singing (e.g., Arroyo-Solis et al. 2013), whereas habitat disturbance or pollution can also influence chorus properties (e.g., Van Oort et al. 2006).

McNamara et al. (1987) proposed that conditions at night are unpredictable such that birds will have energy reserves remaining at dawn that are used for singing. Alternatively, Kacelnik proposed that birds sing at dawn because foraging success is likely to be low at low light levels (Kacelnik 1979). Models varying in overnight energy requirements or foraging profitability over the morning both have support and may influence different components of the chorus (Hutchinson 2002).

## Physiological Factors

We understand very little about physiological control of the dawn chorus. There is a correlation between dawn song output and testosterone level; however, territory occupancy and dawn chorusing precedes this spike in testosterone so the seasonal pattern is not controlled by testosterone (Foerster et al. 2002). Implantations that impair estrogenic and androgenic pathways result in an increase in the number of males not chorusing or lower song rates and males with high testosterone levels have longer dawn chorus songs (van Duyse 2004). Hormones involved in circadian cycles also appear to influence song type choice (Goodson 1998).

## Functions

Song is considered to function to communicate with both mates and rivals. As such, there is considerable research focusing on both these functions. First, recent work shows support for Staicer's et al. (1996) social dynamics hypothesis that males sing at dawn to adjust their social relationships with neighbors. At dawn, males engage in vocal interactions that extend to multiple individuals (e.g., Foote et al. 2010). Males sing near territory boundaries and removal of neighbors results in chorus cessation, which resumes when the neighbor is reintroduced (Liu 2004). High male density leads to earlier singing, higher song rates, and longer choruses (e.g., Xia et al. 2014). Recent work also shows that the dawn chorus clearly plays a role in territory defense. Males begin to sing earlier at dawn when a simulated intrusion begins earlier than typical species specific song (Foote et al. 2011) or sing at higher rates following a simulated intrusion on the previous day (e.g., Amrhein and Erne 2006). The activity of territory prospecting males is also centered around sunrise; thus, there is a value for territory holders to proclaim ownership and for prospecting birds to assess territory occupancy and rival quality (Amrhein et al. 2004).

In terms of social mate attraction, there is mixed support for this function of the dawn chorus. First, the dawn chorus persists after pairing and the chorus may not vary between mated and unmated males (Kunc et al. 2005). Second, Females do not appear to actively search for mates at dawn (Roth et al. 2009). Finally, female removal results in no change in song rates (Otter and Ratcliffe 1993). There is evidence, however, that song could advertise to fertile females for within-pair and extra-pair copulations (Double and Cockburn 2000) or that females would benefit from eavesdropping on vocal interactions of males at dawn as they do during the daytime.

Staicer et al. (1996) proposed that males may sing to stimulate their mate's reproductive development or to guard mates. Both hypotheses predict high song rates or earlier singing near or when females are fertile. Mated males of some species

do begin to chorus earlier or increase song output when mates are fertile compared to during other breeding stages while others do not (e.g., Bruni and Foote 2014; Kunc et al. 2005). Female arrival often results in chorus termination and delaying female emergence results in longer choruses (Otter and Ratcliffe 1993).

The dawn chorus is an honest indicator of quality for both mates and rivals. Male dawn song or chorus properties reflect other measures of male quality and are correlated with pairing date (Murphy et al. 2008), extra-pair mating success (e.g., Kempenaers et al. 1997), are preferred by females in choice-trials (Hoeschele et al. 2010), and are repeatable (e.g., Murphy et al. 2008). Male dawn chorus properties are also correlated with responses to simulated intrusions later in the day (e.g., Poesel et al. 2004). Short-term supplemental feeding studies support the concept of the chorus being an honest indicator of quality limited by energy supply (e.g., Cuthill and Macdonald 1990).

## Heterospecific Interactions

Tropical species that sing at the same time have songs that are more similar to one another than expected by chance and that typically these species are also closely related suggesting that the chorus involves communication between species that compete for resources (e.g., Tobias et al. 2014). However, during the chorus, species avoid overlap by singing after another species stops singing (Popp et al. 1985).

## Chorusing in Other Groups

The chorus of non-avian or non-vocal species appears to similarly be important for territory defense and is affected by similar meteorological conditions (e.g., Whitten 1982). Among anurans, some *Eleutherodactylus* species chorus at dawn and may give more aggressive call types at this time again suggesting an intrasexual function (Stewart and Rand 1991). Cicadas produce a pronounced dawn chorus in the tropics, which is

partitioned by calling height, song frequency, and timing (e.g., Sueur 2002).

## Conclusion

The dawn chorus is influenced by circadian cycles linked to variation in light levels. The main function of the dawn chorus may be intrasexual, but rich information for intersexual assessment is likely also an important component.

## Synonyms

Circadian rhythms; Sleep cycles, Related: Biological rhythms; Internal clocks; Timing

## Definition

An organism's internal physiological and behavioral responses to the predictable 24-cycle of planetary rotation (Adapted from Shettleworth 2010). Foundational work on this topic was done in rodents in the mid-1970s showing that these animals have an endogenous cycle slightly longer than 24-h as measured by an activity wheel

(Rusak and Zucker 1975; Zucker 1976). In the absence of external cues, the animals are said to be free-running, i.e., maintaining their own cycle, which will often be longer or shorter than 24 h. These rhythms to the day/night cycle allow animals to optimize behavior adaptively. Diurnal animals will know when it is day to hunt prey, and nocturnal animals will know when the night arrives in order to avoid becoming prey, if the case may be. These endogenous clocks allow animals to anticipate changes to the day/night cycles even if they live in a darkened cave or burrow. In mammals, it is believed that the suprachiasmatic nucleus (SCN) of the retinohypothalamic pathway drives the biological clock as lesions of this area interfere with rhythms associated with eating and drinking behavior in rats (Stephan and Zucker 1972). Given that animals may be active during the day, night, or throughout various times in a 24-h cycle, we will characterize the changes to both brain and body activities as defined by when animals are active rather than just day and night.

### The “Rest” Cycle

The first few hours of sleep are typified by a release in growth hormone, while thyroid hormone is common at the end of the sleep cycle (Institute of Medicine (US) Committee on Sleep Medicine 2006). The mammalian brain enters two distinct phases of neurological activity during sleep, non-rapid eye movement (NREM), and rapid eye movement (REM) sleep. In humans, NREM sleep is further divided into four stages starting with low amplitude mixed frequency theta waves and progressing to the high amplitude low frequency delta waves associated with slow-wave sleep (SWS). REM sleep was first found in infants and differs from NREM sleep in the low amplitude fast waves accompanied by atony in most warm-blooded animals including cats and humans (Aserinsky and Kleitman 1953; Hodes and Dement 1964; Jouvet 1967; Jouvet and Michel 1959). We can look at sleep as an adaptive state, decreasing our activity at times of increased predator risk, and allowing for activity during

times of optimal foraging, prey availability, or minimizing predator risk (Siegel 2017). A major function of REM may be to allow a rapid arousal from sleep with alertness by means of periodic brainstem activation, and this could account for why the majority of REM takes place in the last third of many mammals’ sleep (Siegel 2017). Memory consolidation is another hypothesis for the function of this pattern of sleep in the rest cycle (Boyce et al. 2016; c.f. Siegel 2001), while sensorimotor system development represents a third hypothesis for REM sleep (see Peever and Fuller 2016).

### The “Awake” Cycle

It is hypothesized that mammals awaken thanks to a hormone-mediated process called the cortisol awakening response (CAR). CAR represents a predictable and marked contrast to the regular functioning of the hypothalamic-pituitary-adrenocortical axis over the diurnal cycle and begins within the first hour after awakening from sleep (Steptoe and Serwinski 2016). Significantly less is known about the processes of the brain that maintain wakefulness throughout the day. Sleep behavior in *Drosophila* can be measured using infrared beams traveling through glass tubes housing the fruit flies. These studies reveal that the circadian neuropeptide pigment-dispersing factor (PDF) plays a role in keeping the animals awake and is regulated through dopaminergic neurons (Potdar and Sheeba 2018). The suprachiasmatic nucleus maintains wakefulness most probably by sending alerting signals. Melatonin induces sleep by inhibiting this portion of the brain, and the chemical’s release is triggered by a decrease in light as the diurnal animal enters the night cycle (Parker and Dunbar 2005).

### The Evolutionary Loss of Regular Day/Night Cycles

In fully aquatic mammalian species, the loss of the penial gland indicates a resultant loss of

melatonin-bases circadian rhythmicity (Lopes-Marques et al. 2018). This is seen behaviorally in beaked whales, where their foraging behavior remains unchanged relative to the day/night cycle (Baird et al. 2008). While bihemispheric slow-wave (BSWS) and REM sleep have been observed in all terrestrial species that have been studied (denoted by traditional body posture, closed eyes, distinctive electroencephalographic [EEG] waves, decreased motor activity, and increased sensory threshold associated with traditional forms of sleep), certain marine mammals and species of birds exhibit unihemispheric sleep (Mascetti 2016; Siegel 2017). These animals have adopted a different strategy for their specific environmental needs, with unihemispheric slow-wave sleep (USWS) in marine mammals and unihemispheric-monocular sleep (Un-Mo sleep) in some birds. In USWS, wakefulness and sleep alternate between the two hemispheres of the brain, and there is no NREM or REM. In the absence of a bilateral high-voltage EEG, SWS (EEGs consisting of low frequency high amplitude waves) is confined to one hemisphere for two or more hours, while the other hemisphere exhibits high and low amplitude waves associated with an awakened state. Un-Mo sleep is defined as alternating states of both unilateral and bilateral eye closure and is considered relevant for anti-predation vigilance (Mascetti 2016; Siegel 2017). In non-cetaceans (namely, seals and birds), unihemispheric sleep is a transitory sleep event mingled with bihemispheric sleep (Mascetti 2016). It has proven difficult to know whether the first whales evolved USWS directly from BSWS/REM sleep (typical of most terrestrial species) or if there was an intermediary evolution with a pattern more closely resembling those of pinnipeds and birds (Lopes-Marques et al. 2018).

## Light Pollution and Its Effects on the Day/Night Cycle

Artificial light has often been associated as a direct cause for insomnia (difficulty initiating or maintaining sleep) in diurnal mammals (Stenvers

et al. 2016). The main trigger for the hypothalamic SCN is light, and it is the SCN that coordinates the sleep-wake cycle (Stenvers et al. 2016). With an increase in light pollution, we are starting to see long-term impacts on many species. Wistar rats introduced to dim light at night were found to significantly reduce SCN output strength causing a reduction in feeding-fasting behavior and the daily amplitude of sleep-wake (Stenvers et al. 2016). It was found that in six species of sea turtles, artificial light had deterred nest seeking on what would have been preferred beaches (Witherington 1997). In cases where nesting did occur on lit beaches, hatchlings that emerged nocturnally would wander inland toward the light sources as they were unable to locate the sea (Witherington 1997). Although many negative effects have been observed as a result of artificial light, other species like bats and birds have used artificial light to improve their performances in prey capture by feeding on the various insects drawn to these light sources (Sol et al. 2013). Other diurnal birds, like gulls and pigeons, have increased their foraging times, expanding their ability to meet daily food requirements (Sol et al. 2013). In blue tits (*Cyanistes caeruleus*) males who sing earlier in the day, by virtue of the presence of artificial light, have increased reproductive success (Kempnaers et al. 2010). Hence, light pollution has long-term consequences leading to both positive and negative fitness effects.
